The development of homotypic versus heterotypic immunity in people remains a complicated and incompletely understood phenomenon. In recent years the highly successful implementation of the monovalent (G1P8) attenuated human rotavirus Rotarix vaccine (RV1) has provided definitive proof that immunization of young children with a single strain of rotavirus can provide substantial protective immunity from infection with multiple other strains and serotypes (see Prevention and Control section later). The lack of correlation between the rather low levels of serotype-specific neutralization responses following vaccination with either RV1 or the bovine reassortant pentavalent RotaTaq vaccine (RV5) and the high levels of protective efficacy induced by these vaccines imply that immunity is not exclusively homotypic and may not be directly linked to neutralizing antibody, at least in the serum.

Large numbers of animal studies have been carried out that either support or refute the hypothesis that rotavirus immunity is fundamentally homotypic in nature. There may be multiple reasons for these contradictory findings including species-specific differences in responses to infection, differences in measures of protection that are dependent on the challenge dose and strain, and differences in measurements of protection (i.e., lack of infection, lack of disease, and reduced disease severity are all possible end points). In any case, from a practical standpoint, it seems clear that some level of heterotypic immunity is frequently induced following primary rotavirus infection in people. Although serotype-specific neutralizing antibodies have been demonstrated in breast milk, the effect of breastfeeding on the occurrence of rotavirus gastroenteritis is controversial, but the weight of the evidence would indicate a real but relatively modest effect that is greatest early in infancy.^{139,283,517,539,599}

It is becoming clear that the innate immune system is also deeply involved in the early events of rotavirus immunity and may help shape the outcome of the B-cell-mediated antibody response to infection (Fig. 45.16).¹⁷⁵ Recent interest in the innate immune system and rotavirus immunity stems from

several important observations. First, one of the rotavirus proteins, NSP1, functions as an inhibitor of interferon production via the degradation of IRF3, 5, and 7 as well as β -transducin repeat containing protein (β -TrCP). Second, this degradation appears to function in a host and cell type-restricted manner. Third, inhibition of interferon signaling in murine models is associated with several enhanced and unusual disease phenotypes. Finally, plasmacytoid dendritic cell (pDC)-secreted interferon in response to rotavirus infection likely enhances the host B-cell response. The bulk of our recent knowledge regarding innate immunity has been derived from *in vitro* and animal studies. A type I interferon response can be detected during active viral replication both *in vivo* and *in vitro*.^{286,429,769} The early host innate immune response to rotavirus infection is dependent on transcription-mediated interferon regulatory factors (IRFs). Rotavirus activation of the innate immune response appears to vary depending on the cell type and viral strain. In human pDCs, interferon production is generally triggered by intact triple-layered particles independently of virus replication and is dependent on the particles containing dsRNA. In the minority of pDCs that are permissive for rotavirus replication, interferon production is down-regulated.¹⁷⁴ In other studies of myeloid dendritic cells (mDCs) from IRF3^{-/-} mice, type I IFN induction is reduced, indicating that IRF3 mediates the response in mDCs. Exposure of mDCs to UV-treated rotavirus induces significantly higher type I IFN levels, however, suggesting that rotavirus-encoded functions also antagonize the interferon response in mDCs, as is the case in fibroblasts and epithelial cells but not in pDCs.¹⁹⁵ There are little data on the innate response to rotavirus in other animal species, but in calves acute rotavirus infection is also associated with down-regulation of interferon-associated pathways.¹⁰

The rotavirus NSP1 protein is responsible for the proteosomal degradation of IRF3, 5, and/or 7 depending on the strain, and IRF degradation is associated with the ability of rotaviruses to suppress the host antiviral interferon response.^{38,39,293,294,404} NSP1 has been proposed to function as an E3 ligase in this regard, although definitive support for this hypothesis is lacking. The role of IRF3 is essential in mediating the interferon responses to rotavirus infection *in vitro* as shown using knock-out murine fibroblasts.⁶⁷¹ NSP1 proteins from selected rotavirus strains can also mediate the degradation of β -TrCP and thereby block activation of NF- κ B and interferon induction; however, a direct demonstration of the role of NF- κ B in mediating interferon responses during rotavirus infection using gene knockouts is lacking.²⁹² Recent studies revealed that the early induction of IRF- and NF- κ B-mediated interferon responses occurs primarily via the cytosolic adaptor MAVS and involves the viral pattern recognition receptors RIG-I and MDA-5 as well as the dsRNA dependent kinase PKR.⁶⁷¹ Additional studies also implicate membrane-associated RIG-I, MDA-5, and MAVS, but not PKR, in rotavirus-mediated innate immunity. Further studies are needed to better understand the cell- and strain-specific roles of these factors and the bases for these differences.⁸³ Rotaviruses may also inhibit STAT1 and 2 nuclear translocation and thereby inhibit the establishment of a complete antiviral state downstream of interferon induction, although the viral factors involved in this function are not yet known.³³⁹

Many of these innate immunity effects appear to be strain specific, and some are clearly cell-type specific as well.²³⁶ For example, in mouse embryonic fibroblasts (MEFs), heterologous

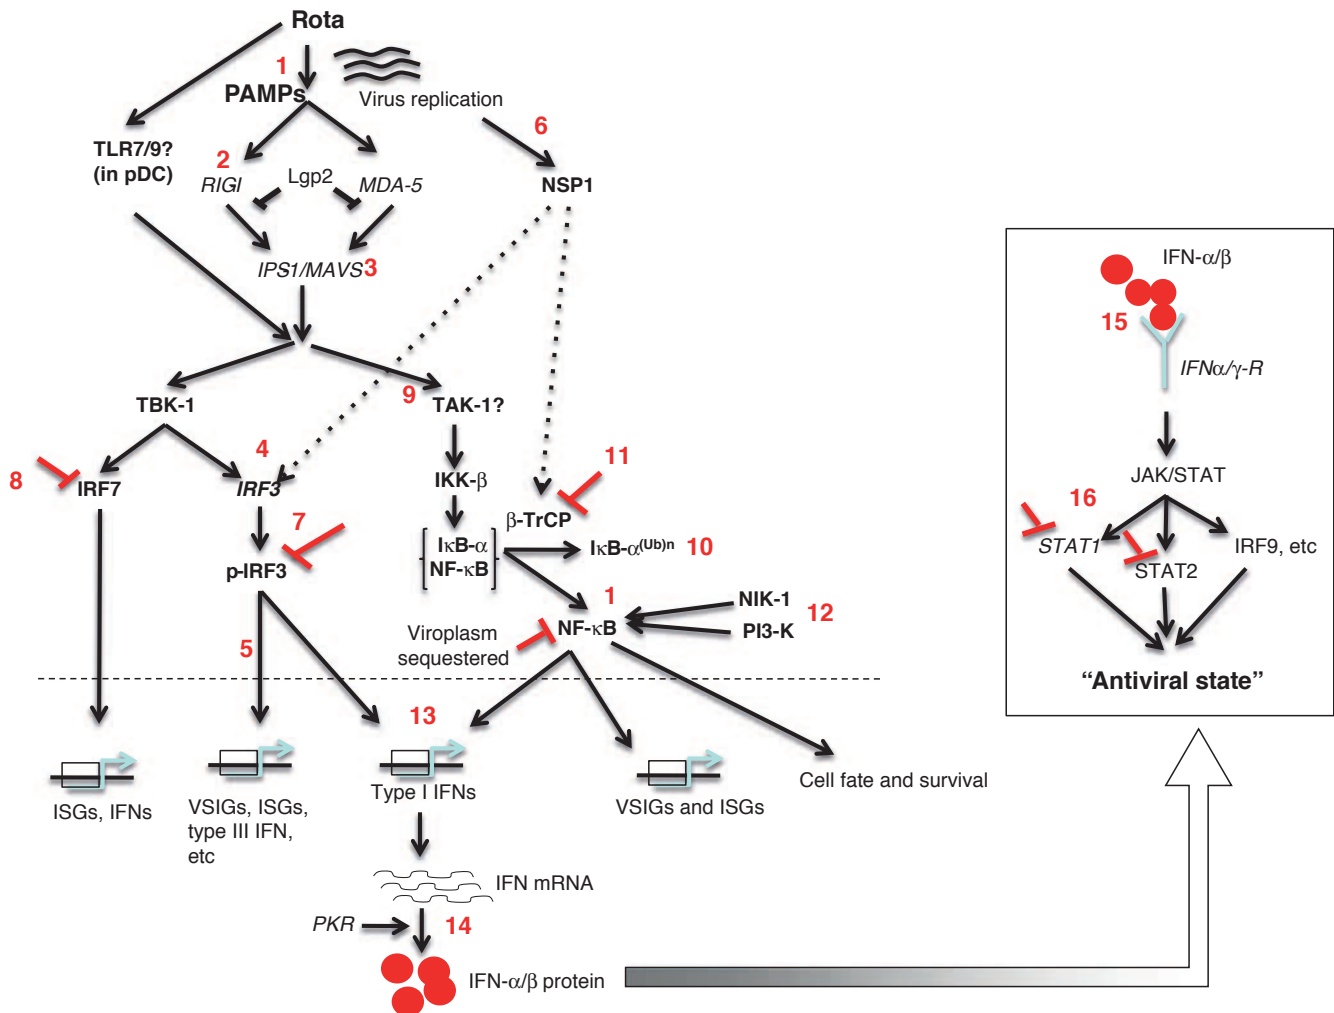

FIGURE 45.16. Rotavirus interactions with the host innate immune system. The numbers refer to interactions discussed below and red lines indicate points of viral interference with indicated pathways; the role of components in *italics* has been validated using genetic knockouts. Viral entry into cells is followed by the generation of pathogen-associated molecular pathways (PAMPs) (1) that are likely by-products of early viral replication. These viral ligands activate the cytosolic pathogen recognition receptors (PRRs) RIG-I and MDA-5 (2), leading to mitochondrial-associated adaptor protein IPS-1/MAVS-dependent activation (3) of the transcription factor IRF3 by the kinase TBK-1 (4). Activated IRF3 translocates to the nucleus where it induces the transcription of ISGs including ISG15, ISG54, ISG56, and so forth early in the replication cycle (5). Viral replication results in the expression of NSP1 (6). NSP1 interacts with and induces proteasomal degradation of IRF3. NSP1 degradation of IRF3 occurs following phosphorylation of the IRF3 carboxyl-terminus in a TBK-1-dependent manner (7) and is IRF3 host origin and cell type dependent. Other IRFs, including IRF5 and IRF7, can also be proteasomally degraded by NSP1 (8), influencing the quality and magnitude of the interferon response. Apart from IRF3, early induction of IFN in RV-infected cells also requires nuclear factor-κB (NF-κB), which is transcriptionally activated by a distinct signaling pathway (9) following the proteasomal degradation of its inhibitory partner, IκB-α (10). Rotavirus strains can also block this part of the induction pathway by NSP1-mediated proteasomal degradation of β-TrCP, an essential co-factor for IκB-α degradation (11), and for some viral strains this is the primary mechanism used to block early IFN secretion. Under certain conditions, activation of NF-κB as well as its relocalization into viroplasm in infected cells has been reported (12), although the relevance to early IFN induction is not clear. Following IRF3- and NF-κB-dependent transcription of IFNs (13), the double-stranded RNA (dsRNA)-dependent protein kinase PKR mediates IFN secretion by an unknown mechanism (14). In pDCs, RV triggers IFN secretion by a process that is likely a result of viral genomic dsRNA-mediated TLR7/9 signaling (steps 1 and 2). The result of IFN secretion from RV-infected cells is the establishment of an antiviral state in bystander cells mediated by signaling through the transcription factors STAT1, STAT2, and IRF9 (15). A second viral strategy exists to counter this phase of the IFN response by sequestration of STAT1 and STAT2 (16), although the viral factors involved are not known. Other interferons including type II and III IFNs may further restrict virus replication and dissemination in the host and may exert different effects depending on the tissue, strain, and stage of pathogenesis.

bovine and porcine rotaviruses fail to effectively degrade cellular IRF3, resulting in IRF3 activation and IFN- β secretion. As a consequence, replication of these viruses is severely restricted in IFN-competent, but not in IFN-deficient, MEFs. On the other hand, homologous murine rotaviruses and a heterologous simian RRV rotavirus efficiently degrade cellular IRF3, diminish IRF3 activation and IFN- β secretion, and are not replication restricted in wild-type MEFs. Mice deficient in interferon signaling (either lacking the interferon type I and II receptors or STAT1) are more susceptible to rotavirus replication and, in some cases, enhanced disease.^{234,743} In a mouse model, lethal biliary disease and enhanced rotavirus systemic replication were seen in interferon signaling-deficient mice infected with the simian RRV strain, and this strain-specific virulence was mapped to rotavirus genes 4 and 5 encoding VP4 and NSP1, respectively.²³⁷ In other studies using a distinct biliary tract disease model dependent on RRV systemic inoculation into newborn mice, analysis of viral reassortants linked only VP4 with the systemic disease phenotype.^{768,769}

The precise mechanism by which the innate immune response restricts rotavirus infection in some species and in some organs remains to be elucidated, but preliminary studies indicate that interferon per se may be more active in suppressing systemic than mucosal replication. Despite the fact that rotaviruses have evolved a strategy to inhibit the interferon response, interferon is actively produced during rotavirus infection *in vivo* in humans, pigs, and other animals.^{286,429,769} Although interferon is clearly present during rotavirus infection in several species, its antiviral effects *in vivo* are not entirely clear. Diarrheal disease in mice appears to be refractory to exogenous interferon therapy, whereas calves treated with recombinant type I interferon appear to have attenuated gastrointestinal disease.^{16,670} Interferon receptor knockout suckling mice do not have enhanced

gastrointestinal disease when infected with a murine rotavirus, but adult STAT1 knockout mice have enhanced replication compared to wild-type mice.²³⁴

Recent studies indicate that primary human pDCs are highly resistant to rotavirus infection but they respond to rotavirus exposure with a brisk and substantial interferon response that is likely initiated by the dsRNA rotavirus genome. This pDC-mediated response might play an important role beyond direct antiviral effects by enhancing the mucosal B-cell response to infection by stimulating B-cell proliferation and enhancing resolution of infection.^{174,175}

There has been less extensive study of primary T- or B-cell responsiveness to rotavirus infection in people than in animal models, and the functional role of these cells or their correlation to protection has been difficult to evaluate in people. Interferon- γ -secreting circulating RV-specific CD4+ and CD8+ T cells are present in very low amounts in children and relatively low amounts in adults, and these cells express the gut homing receptor $\alpha_4\beta_7$.^{366,637} Similarly, primary circulating human B cells have been examined in a number of studies using flow cytometry and ELISpot-based assays.^{367,638,724} These studies show that rotavirus-specific B cells also express intestine-specific homing receptors, and that both naïve and memory rotavirus-specific B cells directed at VP6 are enriched for a CD27+, IgD+, IgM+ subset of cells. The biological role of RV-specific circulating IgM memory B cells is not well understood.

CLINICAL FEATURES

Rotavirus infections produce a spectrum of responses that varies from subclinical infection to mild diarrhea to severe and potentially fatal dehydrating illness (Table 45.6). In one study,

TABLE 45.6 Clinical and Epidemiological Features of Rotavirus Infections

Variable	Description
Age predisposition	Primarily affects young children 3 months to 2 years old in developed countries; younger children affected in developing countries. Adults frequently infected, mostly asymptomatic
Seasonality	Seasonal infection in developed countries with epidemic peaks in cooler months of each year. No seasonality in tropical climates. Vaccination has diminished and delayed seasonal epidemic in United States
Settings	Households, daycare centers, hospitals, schools, favoring person-to-person spread. Occasionally water-borne, especially group B rotaviruses
Asymptomatic infections	Most common in adults and newborns. Can frequently occur in all age groups
Incubation period	Generally 24–48 hours
Symptoms	Sudden onset of vomiting and diarrhea. Diarrheal stools lack blood, mucus, or leukocytes. Fever common
Severity of illness	Overall, more severe than many other diarrheal etiologies, leading to dehydration and hospitalization. Malnutrition increases disease severity
Duration of illness	Typically 3–5 days. Longer illness in immunocompromised
Viral shedding	Peaks 1–3 days after illness onset. Shedding can be prolonged in immunocompromised individuals. Antigenemia and viremia detectable early after infection
Mode of transmission and vehicles	Fecal–oral; aerosol/vomit; contact with fomites Food, water, environmental contamination
Immunity	Repeated infections with or without illness can occur with the same or different strains. Increasing levels of immunity occur with repeated exposures or vaccination
Treatment	Supportive rehydration (oral preferable) therapy to prevent dehydration. Live, attenuated vaccines are available and highly effective in developed countries; vaccine effectiveness is lower in children in developing countries
Reservoir	Humans primarily and animal reservoirs rarely

a comparison was made between (a) the clinical manifestations of 78 patients hospitalized with rotavirus diarrhea and (b) 72 patients hospitalized with a diarrheal illness that was not associated with rotavirus.⁶³⁵ The majority of both rotavirus- and non-rotavirus-infected children had a temperature of 37.9°C or above. Those with rotavirus vomited and became dehydrated significantly more often than those who did not have rotavirus. The mean duration of vomiting was longer in the rotavirus-positive group than in those who did not have rotavirus (2.6 days versus 0.9 days). Rotavirus diarrhea started later than vomiting but lasted longer (mean duration, 5 days versus 2.6 days). After infants and children were hospitalized, diarrhea continued for a mean of 2.6 days (range, 1 to 9 days) in the rotavirus group and 3.8 days (range, 1 to 16 days) in the rotavirus-negative group. The duration of hospitalization ranged from 2 to 14 days, with a mean of 4 days, for the patients infected with rotavirus and for a mean of 6 days (range, 2 to 27 days) for the rotavirus-negative group.

Laboratory findings reflect the high frequency of vomiting and dehydration associated with rotaviral illness.⁶³⁵ Blood urea nitrogen values of greater than 18 mg/dL were observed in 58% of the rotavirus-positive group, and a urine-specific gravity of 1.025 or greater was noted in 71%. A review of liver function tests in children with rotavirus gastroenteritis found that 20% had elevated alanine aminotransferase (ALT) or aspartate aminotransferase (AST) levels.⁷²¹ The pathophysiologic basis for these liver test elevations remains unknown. Over a 5-year period in a Toronto hospital in the early 1970s, rotavirus gastroenteritis was responsible for the death of 21 infants and young children between 4 and 30 months of age.⁹⁸ On arrival at the hospital, 10 of these children were dead, and 10 were moribund and could not be resuscitated. With the exception of two patients, each of the children who died had been healthy previously. Death occurred within 1 to 3 days of onset of symptoms. The major factor causing death was believed to be dehydration and electrolyte imbalance in 16 individuals and aspiration of vomitus in 3. In the remaining two patients, seizures were a contributing factor. Each of the 16 patients tested had a sodium level (serum or vitreous humor) in excess of 150 mEq/L. The rapidly fatal course of untreated severe rotavirus gastroenteritis was underscored by the fact that the parents of 16 of the 20 children who were brought to the hospital had some contact with a physician during the course of the illness. It is important to note that in the more than three decades since this study was published, the mortality rate associated with rotavirus infection in developing and in developed countries has declined substantially primarily due to more aggressive and early rehydration interventions.

Rotaviruses rarely produce a chronic symptomatic infection that involves diarrhea or systemic illness and includes hepatic and renal involvement in children who are severely immunodeficient.^{273,368,554,667,792} Recently, pentavalent vaccine-acquired chronic rotavirus infection and prolonged illness were observed in infants with severe combined immunodeficiency who were inadvertently vaccinated.^{29,569} During chronic infection of immunodeficient children, rotavirus can undergo genomic rearrangements, presumably because of multiple passages at high multiplicity *in vivo*.^{184,353}

Rotaviruses pose a special threat to individuals who are immunosuppressed for bone marrow, stem cell, or small bowel transplantation. In one study of gastroenteritis in a bone mar-

row transplant unit, 8 of 78 patients with gastroenteritis shed rotavirus as the sole pathogen, and 5 of these individuals died.⁸⁰⁹ Rotavirus infections acquired nosocomially have also been associated with severe diarrhea in adult renal transplant recipients.⁵⁸¹ Rotavirus may cause gastroenteritis in small bowel transplant recipients, often in association with acute episodes of rejection.^{5,833} Rotaviruses do not appear to play a disproportionately important role in diarrhea occurring in adults or children infected with human immunodeficiency virus (HIV), reinforcing the findings that rotavirus immunity is most directly influenced by B cells and antibody-related mechanisms.^{312,698}

A temporal association of rotavirus infection with a variety of other disease conditions, both as isolated illnesses or in a single outbreak, has been described.^{331,408,687,780} Because the occurrence of most of these conditions is extremely rare in comparison to the very high incidence of rotavirus infection, it appears that, with the exception of severe disease manifestations in immunocompromised patients, necrotizing enterocolitis and hemorrhagic gastroenteritis in neonates, and pneumato-sis intestinalis in infancy, the association of rotavirus infection with most of the reported conditions is likely temporal and not etiologic.^{97,643,801} Rotavirus infection has been associated with a number of central nervous system conditions, and the virus has been detected in the cerebrospinal fluid on a number of occasions.^{416,449,500,542} However, because viremia is now established to be relatively common, the finding of rotavirus RNA in cerebrospinal fluid does not necessarily imply direct central nervous system replication. It appears that acute rotavirus infection is associated relatively frequently with benign seizures in young children, perhaps in association with the elevated temperature seen in many rotavirus infections.⁵⁰⁰

An unexpected outcome of the effective RV vaccination program has been reports of intussusception after oral administration of the various live attenuated rotavirus vaccines^{92,301,525,568} (see Prevention and Control section); the significance of the temporal association of wild-type rotavirus infection with intussusception deserves further attention. Rotavirus was detected in 20 (33%) of 61 cases of intussusception in two studies, suggesting that wild-type rotavirus might have been the cause^{421,532}; however, three subsequent studies in Australia, France, and Germany failed to find a significant association of intussusception with rotavirus infection.^{521,541,696} Ultrasound examinations of infants with wild-type rotavirus diarrheal illnesses and controls indicate that wild-type rotavirus infections induce a significantly greater number of aggregates of lymph nodes and/or thickening of the ileal wall, both of which may be a prelude to intussusception.^{40,632} Finally, as referenced above and discussed further below, all three of the live attenuated rotavirus vaccines that have been licensed by the Food and Drug Administration, one of which is an attenuated human rotavirus, have been associated with intussusception at low frequencies. Hence, at this juncture, it seems reasonable to hypothesize that virtually any rotavirus infection in children will be etiologically associated with intussusception but that the relatively low rate of etiologic association that might vary from strain to strain or vaccine to vaccine is often so low that it is extremely difficult to identify except in the context of a large vaccination campaign and close monitoring. Recent studies have clearly demonstrated that rotavirus infection is not strictly restricted to the gut and that both viremia and systemic replication are a frequent consequence of natural infection with wild-type rotavirus in both humans and

other animals.^{63,230,618} It is also clear that this systemic phase of infection can be associated with clinical manifestations if the host is immunosuppressed. It is not clear currently whether this systemic phase of rotavirus infection is etiologically associated with any clinical syndromes, like intussusception, in the immunocompetent host.

DIAGNOSIS

The clinical and epidemiologic manifestations of rotavirus illnesses (severe diarrhea, vomiting, dehydration, fever in young children, and seasonality in nontropical areas) are not sufficiently distinctive to permit diagnosis even during a rotavirus “season.” The accurate diagnosis, therefore, requires detection of virus or viral antigen or a virus-specific serologic response. The epidemiologic pattern of rotavirus disease at any one time may strongly suggest this diagnosis, but laboratory confirmation is required to be definitive. Of note, because the primary treatment, rehydration, should be administered on clinical grounds alone and is not dependent on the specific identification of rotavirus infection, the clinical need for definitive etiologic diagnosis is not strong.

Since 1973, many assays have been developed for the detection of rotavirus in stools,⁸⁰⁸ although at present solid-phase immunoassays and RT-PCR-based assays are the primary diagnostic tools. Specimens from the first to the fourth day of illness are optimal for virus detection using traditional assays (e.g., EM or ELISA); however, shedding can continue for up to 3 weeks, depending on the duration of symptoms, and may be detected longer by RT-PCR.^{55,284} Viral shedding as detected by conventional techniques, such as ELISA, usually coincides with the duration of diarrhea, but diarrhea can continue for an additional 2 to 3 days and ELISA positivity can continue past the end of diarrhea.⁶³¹ Initially, direct visualization of stool material by EM was employed for rotavirus detection.^{58,75,398} EM has the advantage of high specificity because rotaviruses have a distinctive morphologic appearance, but there are substantial disadvantages of being relatively low throughput and requiring very expensive equipment. In early studies, direct EM examination of stools permitted detection of rotavirus in 80% to 90% of the virus-positive specimens when compared to immunoassay techniques.⁷⁵ Various methods with higher throughput than EM are now available for the detection of rotaviruses in stool specimens.²⁸⁴

The method of choice in many laboratories is ELISA, because it is sensitive, does not require specialized equipment, is available commercially in validated formats, is relatively inexpensive, and often has a built-in control for nonspecific reactions. Other methods for virus detection, such as counter-immunoelectrophoresis, gel electrophoresis of rotavirus RNA, reverse passive hemagglutination assay (RPHA), and latex agglutination, have been used in the past.⁸⁰⁸ A variety of generally sensitive and specific commercial kits for rotavirus detection are now available primarily using some form of ELISA solid-phase immunoassay format. Enzyme immunoassays have also been developed in research laboratories for detection of group B or group C rotavirus and for measurement of antibodies directed against these viruses.^{258,466}

A dot blot hybridization assay for detection of rotaviruses was developed based on *in situ* hybridization of labeled rotavi-

rus ssRNA transcripts to heat-denatured rotavirus RNA immobilized on a nitrocellulose membrane.²³⁸ The method is highly specific, yielding results concordant with those obtained with other tests such as EM, dsRNA detection, and ELISA.²⁰⁵ In a comparative study of ELISA and dot hybridization for the detection of rotavirus in various dilutions of fecal specimens, the dot hybridization method was 10 to 100 times more sensitive than the confirmatory ELISA but much less practical and has not been generally employed since RT-PCR-based assays became available.

Of the variety of research laboratory techniques that have been used for the detection of group A rotaviruses, the most important, after the solid-phase immunoassay, is RT-PCR, which is highly sensitive and specific and has the added advantage of being able to determine genotypes.²⁸⁴ For example, using an RT-PCR-based assay, virus shedding was detected from 4 to 57 days after diarrhea onset, and 30% of children rotavirus positive at early time points by ELISA shed virus detectable by the assay for 25 to 57 days.⁶²⁷ PCR has also been applied to the detection of group B and C rotaviruses.²⁹¹

It is also possible to recover human rotaviruses from stool specimens directly in cell culture with reasonable efficiency, but this approach is not practical except for specific experimental purposes. This method appears to be approximately 75% as efficient as antigen detection assays using conventional procedures.³²⁹ The efficiency of recovery of virus from rectal swabs using cell culture is considerably less. Growth of rotavirus in tissue culture allows the determination of its serotype by neutralization assay, and rotavirus serotype can now also be reliably predicted by nucleotide sequence analysis of the *VP7* and *VP4* genes. The use of RT-PCR has also enabled the genotyping of rotavirus-positive specimens that could not be typed by ELISA or cultivated directly.²⁴¹

A variety of techniques have been used in the past to measure a serologic response to rotavirus infection, such as IEM, complement fixation (CF) tests, immunofluorescence tests, immune adherence hemagglutination assay, ELISA, neutralization, hemagglutination inhibition, inhibition of reverse passive hemagglutination, enzyme-linked immunospot (ELISpot) assay, and immunocytochemical staining assays. Currently, the most useful assays are the IgA and IgG ELISAs and neutralization assays. The CF method is about as efficient as the other methods for detecting an antibody response in patients between 6 and 24 months of age, but it is not as efficient in adults or in infants younger than 6 months of age and is not generally used today. In infants and adults, IF and IgG, IgA, and IgM ELISAs are more efficient and sensitive. Because IgA does not cross the placenta, a rotavirus IgA ELISA has been the assay of choice in demonstrating serologic responses in infants younger than the age of 9 months who generally possess passively acquired maternal IgG antibodies.^{458,459} This assay can also be used for measuring antibodies in saliva, duodenal fluids, and stools⁴⁵⁹ and is the assay employed in most studies of seroresponse rates to rotavirus vaccines.¹⁸¹ Fecal rotavirus IgA antibody levels exhibit a direct relationship with duodenal IgA antibody levels³¹⁰ but are difficult to standardize. In addition, in one study a rise in fecal rotavirus IgA antibodies measured by ELISA correlated with an intestinal neutralizing antibody response.¹⁵⁴

It has been suggested that copro-IgA conversion in feces obtained weekly would be a more sensitive indicator of rotavirus reinfection than seroconversion or detection of virus

shedding,¹⁵² but difficulties in accurately and reproducibly monitoring fecal IgA levels have restricted the use of this assay. Based on observations from a clinical study in infants and children, rotavirus IgA in serum has been suggested to reflect the immunologic status of the intestinal lumen with respect to rotavirus antibody.^{172,338} Several studies have correlated levels of antirotavirus serum IgA with protection, although this association is not absolute.^{338,549,747} Early diagnosis can also be made by ELISA, which can detect a specific serum IgM response during the acute phase of illness.¹⁷²

Neutralizing antibodies can be detected by plaque reduction, neutralization of fluorescent foci, neutralization of virus as determined by quantitation of viral antigen by ELISA, or inhibition of cytopathic effect in roller-tube cultures.³⁹² Neutralization assays provide the serotype of infecting rotavirus and information about the development of a serotype-specific or heterotypic antibody response. A competition solid-phase immunoassay that measures epitope-specific immune responses to individual rotavirus epitopes associated with serotypes was shown to be useful in evaluating immune responses at the level of individual epitopes. This technique uses the test serum as the blocking reagent and the individual mAbs as the detecting reagent.⁶⁸⁰

Treatment

The primary aim of treatment of rotaviral gastroenteritis is to replace fluids and electrolytes lost by vomiting and diarrhea. Intravenous fluid administration has been used successfully for many years in treating dehydration from diarrhea. Because facilities and equipment for parenteral administration of fluids and electrolytes are not readily available in many parts of the world, intensive efforts have been made to evaluate the efficacy of oral fluid replacement therapy, which is mechanistically based on the specific coupling of sodium and glucose transport in the intestine.^{7,22,652,661} Various formulations of oral rehydration salts (ORSs) with added glucose or a glucose substitute are effective in the treatment of dehydration caused by rotavirus diarrhea, with some minor variations in their efficacy. For example, in a double-blind study, oral rehydration therapies with electrolyte solutions containing either glucose or sucrose were highly effective for treatment of rotavirus gastroenteritis.⁶⁵³

The standard WHO oral glucose electrolyte formula is composed of the following: 90 mM sodium, 80 mM chloride, 20 mM potassium, 10 mM citrate, and 111 mM glucose, resulting in an overall osmolality of 310 mOsm/L.^{1,22} Bicarbonate (30 mM) can be substituted for citrate. An ORS solution containing a reduced sodium concentration was found to be more effective for treatment of infants with noncholera diarrhea than the standard WHO solution in a multicenter trial.¹²⁸ The reduced-sodium solution contains 75 mM sodium, 65 mM chloride, 20 mM potassium, 10 mM citrate, and 75 mM glucose, resulting in an overall osmolality of 245 mOsm/L (reduced osmolality ORS solution). After correction of the initial calculated fluid loss by oral rehydration solution, either water or fluids without added electrolytes (e.g., breast milk or some other form of low-solute feeding) should also be administered orally in addition to the oral rehydration solution. When this regimen is used, both continued diarrheal fluid and electrolyte losses will be replaced and normal daily fluid requirements will be maintained.²²

Rice-based solutions have been compared with glucose-based oral rehydration solutions in infants and young children

hospitalized with mild to moderately dehydrating diarrheal illnesses associated with various pathogens, including rotavirus.⁵⁹⁸ Each was found to be effective, but the rice-based solution was more effective in decreasing total stool output and increasing absorption and retention of fluid and electrolytes. Both glucose-based and rice-based oral rehydration solutions were effective in treating mild to moderate dehydration caused by various pathogens, including rotavirus, in another study.⁵¹³ Recent studies from a number of investigators have demonstrated that zinc supplementation improves the therapeutic value of ORS, and this addition is now recommended by the WHO for children with acute diarrhea.²² Several other additives to the ORS formulation are currently under investigation; these include lactoferrin and lysozyme and various amino acids including glycine, alanine, and glutamine. When/if oral rehydration does not correct the fluid and electrolyte loss, or if the patient is severely dehydrated or in shock, intravenous fluids must be given immediately. Oral rehydration therapy should not be given to patients with depressed consciousness because of the possibility of fluid aspiration.

The American Academy of Pediatrics (AAP) does not currently recommend the use of loperamide, anticholinergic agents, bismuth subsalicylate, adsorbents, or lactobacillus-containing compounds for the management of the acute diarrhea in children 1 month to 5 years of age. The use of opiates, as well as opiate and atropine combination drugs, for treatment of children with acute diarrhea is also contraindicated by the AAP.¹

Human milk, containing rotavirus antibodies, has been used successfully for treatment of children who are immunodeficient and who have chronic rotavirus infection and illness.⁶⁶⁷ In contrast, colostrum or milk concentrate from cows immunized with human rotavirus was not effective for the treatment of acute rotavirus gastroenteritis in children, although a decrease in the duration of virus shedding was observed.²⁰² Daily oral administration of rotavirus antibody-containing bovine colostrum, however, appeared to exert a preventative effect during an orphanage outbreak of rotavirus diarrhea.²⁰² The effect of a single oral dose (300 mg/kg body weight) of gamma globulin in infants hospitalized for gastroenteritis (70% rotavirus associated) was evaluated in a double-blind, placebo-controlled trial. The treatment group had a significantly shorter duration of diarrhea, viral excretion, and hospital stay.³¹⁴ In another study, the oral administration of human serum immunoglobulin to two infants with prolonged rotavirus diarrhea of 4 or 7 months' duration was effective in clearing the virus and the associated diarrhea.³¹⁶ Also, bovine colostrum prepared by immunizing pregnant cows with human rotavirus strains of G1, G2, G3, or G4 specificity was given orally to patients 4 to 6 months of age with rotavirus diarrhea and was found to significantly reduce the duration and frequency of diarrhea as well as the need for oral rehydration solution.^{326,666} A randomized double-blind study in rotavirus-infected young children using antirotavirus immunoglobulin produced in eggs showed a modest improvement of diarrhea that was associated with earlier clearance of rotavirus from stools.⁶⁶⁵ Despite the generally positive results observed with immunotherapy for rotavirus disease, the cost considerations versus vaccination make this approach impractical except perhaps in the case of chronic rotavirus infection in the severely immunocompromised.

Recently, in murine rotavirus model studies, lactobacillus-expressed, llama-derived immunoglobulin domains, which

would be much easier to produce than immune bovine colostrum, were shown to have modest therapeutic as well as preventative effects on acute infection.⁵⁵⁹ It is noteworthy that despite the fact that (a) the first studies on oral immunotherapy for rotavirus diarrhea were done over 25 years ago and (b) a variety of studies have shown at least some degree of efficacy, this therapeutic approach has remained experimental and has never gained broad acceptance. The reasons for this are multifactorial, but most likely the primary reason is the lack of a commercial product, probably due to unacceptable cost and production issues.

Bismuth subsalicylate (BSS) given orally five times a day at 20 mg/kg for 5 days as an adjunct to rehydration therapy shortened the course of disease in children 4 to 28 months of age hospitalized with acute rotavirus diarrhea in a prospective double-blind, placebo-controlled treatment trial.⁶⁹¹ Because of the association between the use of salicylates and Reye syndrome, the possibility of an association with BSS or other nonacetylsalicylic acid salicylates and the disease was reviewed and none was found. However, the AAP does not recommend the use of bismuth subsalicylate for the management of acute diarrhea in the 1 month to 5 year age group.¹

The efficacy of several broad-spectrum antiviral agents has been examined as inhibitors of rotavirus replication *in vitro*. In one survey, various adenosine analogs were found to have antirotavirus activity, and it was suggested that this activity resulted from inhibition of S-adenosylhomocysteine hydrolase, an enzyme involved in regulating methylation required for production of functional viral mRNA.⁴¹⁵ Double-blind, placebo-controlled studies of racecadotril, an enkephalinase inhibitor (not available in the United States but available in a variety of European and South American countries) found the compound was effective in the treatment of hospitalized pediatric patients with watery diarrhea (including rotavirus diarrhea) when used in conjunction with oral rehydration therapy.⁶⁵⁶ Orally administered nitazoxanide (a broad-spectrum anti-infective drug) reduced the duration of severe rotavirus diarrhea in two studies of hospitalized pediatric patients.^{642,722} Several recent studies have supported a beneficial role for probiotic therapy for rotavirus diarrhea, and one direct comparison of probiotic with nitazoxanide showed that both had modest therapeutic effects, with nitazoxanide being somewhat more effective.^{148,228,299,722} Each of these preliminary therapeutic studies needs confirmation in a variety of clinical settings as well as distinct subject population groups. Importantly, the recent advent and widespread use of several safe and effective rotavirus vaccines has substantially diminished the need for an effective rotavirus therapy except in specialized circumstances such as severely immunocompromised infants or transplant patients.

PREVENTION AND CONTROL

Vaccines

General Principles and Background

Epidemiologic and hospital-based studies worldwide over the past 3 decades clearly demonstrate the substantial burden of disease associated with rotavirus infection and strongly support the need for prevention in both developed and less developed countries.^{275,469,692} The primary aim of a rotavirus vaccine should be to prevent severe rotavirus gastroenteritis during the

first 2 to 3 years of life, the period when rotavirus disease is most serious and takes its greatest toll. This is a realistic goal because, while natural infection does not provide complete protection against a subsequent reinfection and disease, in general disease severity is substantially reduced during secondary and subsequent infections.^{57,747} Considerable evidence from studies in animals indicates that the presence and quantity of rotavirus-specific antibody in the lumen of the gut plays a critical role in resistance to rotavirus disease.²⁵² Other studies from children have associated elevated levels of fecal antirotavirus IgA with resistance to illness.¹⁵¹ These observations suggest that the effectiveness of a rotavirus vaccine largely depends on its ability to stimulate transport of antibodies into the gut lumen or to stimulate local production of antibodies. Currently, perhaps the most reliable and well-documented method of stimulating local intestinal immunity is thought to be infection or immunization in the intestine. For this reason, most efforts to date have focused on live attenuated vaccines that are administered orally.

Longitudinal studies have shed light on the resistance to disease induced by prior, naturally acquired rotavirus infection. Reinfection within the first few years of life is common, and an infant who has had a primarily rotavirus infection, whether severe, mild, or asymptomatic, usually experiences a milder illness during reinfection. The level of protection induced by primary and subsequent reinfections may be less in some poor countries than in the developed world.^{47,57,275,749,750} In one epidemiologic study, neonates who were infected in a newborn nursery during the first 14 days of life experienced almost 50% fewer rotavirus diarrheal episodes during the next 3 years compared to a cohort of infants who had not been infected with rotavirus in the nursery.⁵⁷ In a large cohort study in Mexico in which 200 infants were followed from birth to 24 months of age, 96%, 69%, 42%, 22%, and 13% of them experienced one, two, three, four, or five rotavirus infections, respectively. Significantly, no child developed a moderate to severe diarrheal illness after the second infection, indicating that wild-type infection effectively “vaccinated” these young children against severe subsequent disease. Protection was greatest against severe disease and considerably less against mild disease or simple reinfection.^{746,747} In general, second infections were caused by a different G serotype ($P = 0.054$), but any primary infection appeared to offer substantial protective efficacy against severe disease on reinfection, irrespective of serotype. Recently, a similar prospective study from India demonstrated a substantially smaller protective effect from primary natural infection on subsequent reinfection, mirroring what has been observed with rotavirus vaccination in parts of Asia and Africa.²⁷⁴ In this study primary rotavirus infection occurred early in life, the levels of reinfection were high, and protection against moderate or severe disease increased with the order of infection but was only 79% after three infections. Unexpectedly, there was no evidence of homotypic protection.

Because wild-type infection has been shown to be a moderate to relatively effective inducer of immunity against subsequent severe diarrheal illness, the key issue that needed to be resolved in designing a live viral vaccine was an effective means of attenuating virulence while retaining immunogenicity. Rotavirus infection primarily involves the mature villus tip epithelium of the small intestine. Experience with several other viruses that cause mucosal infections (e.g., influenza A

virus and respiratory syncytial virus) indicated that attenuation is frequently a reflection of decreased viral replication in the target organ, which is also the site at which infection is initiated. However, decreased replication is frequently associated with decreased immunogenicity. Hence a delicate balance must be achieved between satisfactory attenuation and satisfactory immunogenicity in the design of live viral vaccines, especially those that immunize at the primary site of natural infection.

Epidemiologic studies worldwide have revealed that a very wide range of serotypically distinct human rotaviruses are currently in circulation but the great majority of infections (over 80%) are caused by viruses with just five G serotypes (1, 2, 3, 4, and 9) and two or three P serotypes.^{267,660,797} As discussed earlier, the relationship between this serotype diversity and protective immunity has been an area of intense investigation almost since the discovery of human rotaviruses. Obviously, the development of an effective vaccine is dependent on its ability to provide significant protection from many, if not all, rotavirus serotypes that infants are likely to encounter. Epidemiologic studies in children clearly provided evidence to support the development of both homotypic and heterotypic immunity following natural infection with the biggest point of contention being the breadth and duration of the heterotypic response.^{15,47,124,185,252,747,771} Unfortunately, experimental studies in animals, which have demonstrated both homotypic and heterotypic immunity depending on the experimental design, viral strain, immunogen examined, and species under study, have not provided a definitive answer vis à vis the design of an optimal human vaccine.²⁵² In gnotobiotic calves and piglets, heterotypic immunity is seen between an animal rotavirus (bovine, serotype G6) and a human rotavirus (serotype G1).^{798,834} Calves infected *in utero* with bovine rotavirus resist challenge with a heterotypic and heterologous human rotavirus at birth. In other studies in piglets and calves, however, only homotypic immunity was demonstrated, although in certain instances the severity of diarrhea was reduced following heterotypic challenge.^{265,523,794,796} Of note, many of these early cross-protection studies did not carefully and quantitatively evaluate the ability of heterotypic immunization to diminish disease severity; instead, success was defined as total elimination of disease following challenge. Given that the goal for human vaccines is the reduction of disease severity, this represents an important design defect in some of the investigations and restricts the utility of these studies to inform the human vaccine design approach.

The early development of live attenuated rotavirus vaccines was deeply influenced by considerations as to whether an effective vaccine would need to contain multiple serotypes or whether a monotypic vaccine could generate sufficient heterotypic immunity to be effective. As the subsequent discussion will indicate, after multiple studies with multiple vaccine candidates, we now have field efficacy evidence from around the world that both monotypic and multitypic live attenuated rotavirus vaccines can be successfully used in people and that both approaches lead to successful vaccines that substantially reduce rotavirus morbidity and mortality.^{181,186,281,309,375}

Initial Monovalent Animal Rotavirus ("Jennerian") Vaccine Candidates

Current production of licensed rotavirus vaccines is based on strategies that ranged from cell culture cultivation of strains

obtained from either humans or animals to the application of genetic techniques to produce reassortants between human and animal rotaviruses. The initial evaluated approach was based on the method first reported by Edward Jenner in 1798 for vaccination of humans against smallpox (see chapter on Smallpox). Jenner used a live, antigenically related animal virus, cowpox, to immunize humans against variola virus, the etiologic agent of smallpox. This strategy is based on the well-known tendency of many microbial pathogens to be host-range restricted. As such, viral strains isolated from one species frequently replicate inefficiently in other species; however, in some cases, this restricted replication capacity is sufficient to induce protective immunity. The usefulness of a *Jennerian* strategy for human rotavirus vaccination was suggested by the early observation that human and animal rotaviruses share a major common antigen.^{247,398,793} The potential feasibility of this approach was shown during animal studies in which calves administered a bovine rotavirus (serotype G6) *in utero* were protected from illness following challenge at birth with an entirely heterotypic human rotavirus of serotype G1 specificity.⁷⁹⁸ It should always be kept in mind, however, that all *Jennerian* or modified *Jennerian* rotavirus vaccines are based on cell culture–adapted animal strains and that the actual cell culture adaptation likely also contributes to their attenuated phenotypes in humans.

The initial rotavirus vaccine studies in people involved a cell culture–passaged, cold-adapted, serotype G6 bovine rotavirus (strain NCDV [RIT 4237]).^{749,752} This highly attenuated, orally administered G6 monovalent vaccine induced over 80% protection to clinically significant diarrhea from serotypically distinct human strains in infants and young children in two separate efficacy trials in Finland.^{750,751} In another study, vaccination of neonates with the candidate vaccine modified the severity of rotavirus diarrhea during the 16-month follow-up period.⁷⁶¹ Following two doses—one in the neonatal period and a second dose 7 months later—the vaccine had a protective efficacy of 43% against any rotavirus-caused diarrhea and 89% against severe rotavirus-induced diarrhea.⁷⁶² However, the RIT 4237 vaccine candidate failed to induce significant protection against rotavirus diarrhea in trials in several developing countries and, as a consequence, further evaluation of this vaccine was not pursued.^{173,327,662,673}

Another serotype G6 bovine rotavirus strain, designated WC3 (Wistar calf), also demonstrated variable protective efficacy in several studies in the United States and overseas.^{48,77,135,136} For example, in infants 3 to 12 months of age in Philadelphia, its protective efficacy (when serotype 1 human strains were predominant) was 76% against any rotavirus-caused diarrhea and 100% against moderate to severe rotavirus diarrhea.^{135,136} In contrast, during later studies, the vaccine was less effective: in subjects from Cincinnati and the Central African Republic, the vaccine exhibited a protective efficacy against moderate to severe rotavirus diarrhea of 35% to 41%; and in China protective efficacy was 50% against any rotavirus diarrhea.^{48,268} Because of the relatively low and variable levels of protection, the vaccine was withdrawn from further study in its monovalent formulation. However, this strain was subsequently used to provide the genetic backbone for a safe and effective pentavalent human-bovine reassortant rotavirus vaccine (RotaTeq, RV5, see later) that was first licensed in the United States in 2006 and is now used worldwide.

Another animal rotavirus strain, the simian G3 RRV strain MMU 18006, was studied extensively as a monovalent *Jennerian* vaccine candidate.^{396,509} The RRV vaccine has been evaluated in both developed and developing countries. Although in some settings (such as in children older than 3 months of age on initial vaccination) it induced a mild to moderate transient febrile response in about one-third of the target population of infant vaccinees, it appeared to be more antigenic than the NCDV (RIT 4237) bovine rotavirus vaccine candidate.^{458,753} The RRV vaccine, however, was much less reactogenic in neonates or children younger than 3 months of age, presumably because the higher levels of maternal antibody inhibited vaccine replication.²⁴⁸ The RRV vaccine, like the other candidates, was administered orally, usually following ingestion of buffered formula, or buffer alone, to protect the virus from partial or total inactivation by stomach acid.⁵⁹⁴ In a field trial in Venezuela, the protective efficacy of the RRV vaccine in infants 1 to 4 months of age was 83% against any rotavirus diarrhea and 90% against the most severe illnesses. Results of efficacy trials were also encouraging in Maryland, Sweden, and Finland, but the vaccine failed to protect young infants in New York State or in Arizona; furthermore, it induced only a low level of protection (29%) in infants 2 to 5 months of age in Maryland.^{129,290,626,662,760} The basis for the variable protective efficacy in these studies was never clearly demonstrated, but the vaccine appeared to work best against homologous G3 strains and less well against heterologous strains.

Another pure *Jennerian* vaccine, a lamb rotavirus strain LLR (G10P[12]), is currently produced by the Lanzhou Institute and was licensed for human use in China in 2000. Postlicensure prospective, double-blind, and randomized evaluations of efficacy have not been completed for this vaccine. However, a retrospective case-control study concluded that one dose of the LLR vaccine was moderately effective (81%) in preventing rotavirus gastroenteritis in children 2 to 11 months of age but not effective when administered to children older than 12 months of age. The vaccine is currently not included in the national immunization program in China, and its efficacy level has not been studied outside China.^{79,257}

Initial Quadrivalent RRV-based Reassortant “Jennerian” Rotavirus Vaccine

Failure of the RRV vaccine to reproducibly induce high levels of protection in young infants against heterotypic rotavirus strains suggested that the initial strategy for development of a monovalent *Jennerian* rotavirus vaccine might require modification. As a consequence, the *Jennerian* approach to rotavirus immunoprophylaxis was altered. The *modified Jennerian* approach was used to produce a quadrivalent (RV4) RRV-based vaccine that incorporated the VP7 specificity of each of the four epidemiologically important human G serotypes coupled to the attenuation phenotype of RRV.^{394,396,509} This approach was also used to create the bovine WC3 vaccine (see later). This approach is enabled by the segmented genome of rotaviruses and by the ability of these viruses to undergo gene reassortment with high frequency during mixed infection.^{304,306} Virus reassortants for use as vaccine candidates have been isolated from cell cultures co-infected with a cultivatable, wild-type animal virus (RRV, bovine WC3 or bovine UK rotavirus [see later]) and selected human rotavirus.^{332,399,507,508} Antisera against the animal rotavirus parent were sometimes used to select specific

virus reassortants with the appropriate human VP7 or VP4. It was generally possible to isolate reassortants that derived only one gene segment encoding VP7 or VP4 (in the case of WC3) from the human rotavirus parent and the 10 other genes from the animal parent. In this manner, starting with the simian RRV strain, single human rotavirus gene substitution reassortants were isolated that possessed the human (or rhesus in the case of G3) rotavirus gene for VP7 of serotypes G1, G2, G3, or G4 on a background of 10 animal rotavirus genes.^{507,508}

As expected, the RRV-human reassortants exhibited G1, G2, G3, or G4 neutralization specificity, similar to the most common human rotavirus serotypes.⁵⁰⁷ Phase I studies indicated that each of the RRV-human rotavirus reassortants alone or in a quadrivalent formulation were similar to its RRV parent with respect to attenuation and immunogenicity.^{397,582} Individual reassortants or the quadrivalent vaccine formulation has been evaluated for efficacy in more than 9,500 infants and young children worldwide. The individual reassortants, D_xRRV (serotype G1) or DS-1_xRRV (serotype G2), each induced 67% protection against serotype G1 diarrhea in Finland.⁷⁶³ In Rochester, New York, the D_xRRV vaccine induced 77% protection and the RRV vaccine induced 66% protection against predominantly serotype G1 diarrhea.⁴⁶⁸ Protection against serotype G1, following immunization with serotype G3 or serotype G2 reassortants, strongly suggested that heterotypic immunity could be induced following monovalent heterotypic immunization. Despite the fact that several studies supported the use of a monovalent *modified Jennerian* RRV vaccine candidate, the weight of the evidence from multiple studies implied that a multivalent formulation was more likely to be reproducibly efficacious. Therefore, several pivotal, randomized, double-blinded phase III trials were carried out in developed and less developed populations with the quadrivalent RRV-based reassortant formulation (RV4).

In three large-scale efficacy and safety trials of RV4 in Finland, Native Americans in the United States, and a poor urban population in Venezuela, vaccine efficacy ranged from 48% to 68% against any rotavirus-caused diarrhea. Importantly, efficacy against severe rotavirus diarrhea reached 91% in Finland, 88% in Venezuela, and 69% in Native Americans.^{377,378,583,663} A transient low-grade fever of greater than 38°C (rectally) was observed in up to 29% of the vaccinees, but there was no statistically significant increase in intussusception seen in patients who received vaccine compared to controls in these large phase III trials.

In 1998, based on the safety and efficacy evidence from the major clinical trials of RV4, the FDA granted a biologics license to Wyeth Laboratories for the manufacture and distribution of RV4 (RotaShield) for the immunization of infants at 2, 4, and 6 months of age. The vaccine was recommended for universal vaccination in the United States and given to almost 1 million young children. In 1999, less than a year after licensure, the Centers for Disease Control and Prevention (CDC) reported that between September 1, 1998, and July 7, 1999, 15 cases of intussusception had been reported to the Vaccine Adverse Events Reporting System (VAERS) following administration of RV4.¹⁰⁴ Based on this initial signal, the CDC and the AAP recommended that administration of rotavirus vaccine be postponed pending availability of more data and analysis.¹⁰⁴ Subsequently, the CDC reported that in case-control and case series studies, there was a very significant temporal association

between RV4 vaccination and intussusception during the first 2 weeks after the first vaccine dose. This observation was translated to an estimate of attributable risk of intussusception following vaccination of up to 1 in 2,500, or approximately 1,600 excess cases of intussusception in a full national vaccination program.^{3,525} In 1999, after reviewing the available risk estimate data at the time, the Advisory Committee on Immunization Practices (ACIP) withdrew its recommendation¹⁰⁵ and the RV4 vaccine rapidly disappeared from the marketplace.

Twelve years after the withdrawal of RotaShield, continuing controversy exists in scientific and lay publications on its fate and the level of actual risk associated with vaccine administration.^{52,142,275,324,389,479,524,526,625,784} Central to this discussion is the lack of agreement on the actual attributable risk of intussusception from RV4 as well as the estimate of the effect of the RV4 withdrawal decision on developing countries where more than 500,000 infants and children younger than 5 years of age die annually from rotavirus diarrhea.^{278,301} Recent findings demonstrate that the two currently licensed rotavirus vaccines (RV1 and RV5, see later) also are associated with a transient increased risk of intussusception further and so call into question the advisability of the RV4 vaccine withdrawal. Since the RV4 withdrawal, the risk estimate associated with this vaccine has decreased substantially, with a consensus estimate of risk of intussusception now at 1:10,000 excess cases.^{524,525,588} After RV4's withdrawal, other investigators analyzed population-based hospital discharge data and reported an attributable risk of 1:32,000 to 1:302,000 excess cases of intussusception among the target population of infants 45 to 210 days of age, far less than initial estimates.^{524,685} Further complicating the analysis is the observation that age at vaccination was likely an important confounding factor in the rare occurrence of intussusception following RV4 use.^{399,686} Thus, the use of *catch-up vaccination* of older infants who received the first dose of RV4 later than the recommended age of 2 months was associated with a disproportionate number of vaccine-associated cases of intussusception that were observed in the CDC case-control study.⁶⁸⁶ Avoidance of initial vaccination of infants older than 3 months of age and vaccination during the relatively refractory period of the first 2 months of life may have substantially reduced or eliminated the risk of intussusception with the RV4 vaccine, although the issue of age dependence of intussusception following RotaShield administration remains controversial.^{53,120,399,565,686}

The Two Major Currently Licensed Live Rotavirus Vaccines

Despite the issues raised by the withdrawal of the RotaShield vaccine, work on other alternative live, attenuated vaccine candidates continued with vigor.^{280,332,548} Two separate but parallel approaches were pursued. Initial studies with a monovalent rotavirus vaccine (RV1) derived from a virulent human rotavirus strain 89-12 with G1:P1A[8] serotype specificity were continued. Unlike the *Jennerian* candidates, this strain's attenuation was based only on multiple tissue culture passages.^{46,593,645} In a pivotal efficacy study that included more than 17,000 infants and young children who received two oral doses of vaccine or placebo at 2 and 4 months of age, the vaccine was highly effective (84.7%) at preventing severe rotavirus gastroenteritis and hospitalization (85%).⁶⁴⁵ This vaccine provided a high level of protection against G-P homotypic G1P[8] strains (90.8%) and G heterotypic, P homotypic

G3P[8], G4P[8], and G9P[8] strains as a group. It has also, in a number of separate, postlicensure studies, generally afforded substantial protection against the entirely heterotypic G2P[4] strains.^{149,382,445,756} There are reports, however, showing a lack of protection against G2 strains.⁶⁸⁹

Because of the previous experience with RV4 and the increased incidence of intussusception in the 2 weeks after initial vaccination, the safety arm of the RV1 pivotal phase III trials included more than 60,000 infants, of whom one-half received the vaccine and one-half the placebo. A temporal link with intussusception was not observed in this very large randomized vaccine safety study.^{445,645} Of note, the mean age of the vaccinees at the time of the first dose with RV1 was 8.2 weeks, an age when the background rate of intussusception is very low. Given the high level of efficacy and safety observed in pivotal phase III trials around the world, this monovalent attenuated human rotavirus vaccine, manufactured by GlaxoSmithKline under the trade name Rotarix, was first licensed for use in Mexico, the Dominican Republic, and Brazil in 2005 and in the European common market countries in early 2006, and is currently licensed in more than 110 countries around the world.

At the same time when Rotarix was under development, the *Jennerian* bovine rotavirus candidate strain WC3 (G6:P7[5]), described earlier, was being used to provide the genetic backbone for a series of reassortants with selected human strains to create a pentavalent *modified Jennerian* vaccine RV5. This approach was taken because of the variable protective efficacy achieved using WC3 alone or using monoreassortants of WC3. Five individual WC3 reassortants were formulated into a pentavalent vaccine containing G1 through G4 VP7s and a single P1A[8] VP4.^{332,333} This approach was similar to that taken for the development of RotaShield except that the genetic backbone was derived from a bovine rotavirus rather than a monkey strain and the vaccine contained an additional component strain that expressed a human VP4 protein as well as the four component reassortant viruses expressing various serotypically distinct (G1 to G4) VP7 proteins.

In a pivotal efficacy study that included more than 5,000 infants and young children who received three oral doses of RV5 or placebo at 2, 4, and 6 months of age, the vaccine was highly effective (74%) in preventing any rotavirus gastroenteritis as well as severe gastroenteritis (98%).⁷⁵⁹ It provided a high level of protection against G1, G2, G3, G4, and G9 serotypes. Because of the previous experience with RotaShield and intussusception, a very large safety component of the phase III trial was undertaken that included more than 68,000 infants, of whom one-half received the vaccine and one-half the placebo. A temporal link with intussusception was not observed. Of note, in this safety study the mean and median ages of vaccinees were 9.8 and 10 weeks, respectively, at the time of the first dose; in this age range the background rate of intussusception is very low. This *modified Jennerian* pentavalent vaccine (RotaTeq) is manufactured by Merck and was licensed for use in the United States in early 2006. RotaTeq is recommended for routine use in infants at 2, 4, and 6 months of age by the ACIP.⁵⁶¹ It is now licensed in over 100 countries around the world.

Postlicensure Safety and Efficacy Studies of Rotarix and RotaTeq

In the 5 years since the RV5 and RV1 vaccines have been licensed, these vaccines have been used broadly across the

United States, Central and South America, and, to a somewhat more variable extent, Western Europe.²⁷¹ This has allowed investigators to examine the performance in terms of both safety and efficacy of the two vaccines in an actual practice as opposed to controlled clinical trial settings. These phase IV postlicensure studies in high- and moderate-income countries have confirmed and extended the highly promising results from the phase III trials.^{13,67,93,567,579,609,715,716,754,755} In the United States following the introduction of RV5 in 2006, there has been a continued and sustained decline in rotavirus detection through 2010 as vaccine coverage has increased. This decline has been seen in all regions and has been associated with substantial decreases in hospitalizations and emergency department and outpatient visits and a progressive delay in the timing of the peak week of the annual rotavirus epidemic.^{67,579,715,716} A cost-effectiveness study concluded that although, at current vaccine prices, routine vaccination is unlikely to be cost saving, it should still be considered a highly cost-effective intervention.⁷⁸⁹ A similar beneficial effect has been reported from Australia where both RV1 and RV5 are used.⁹³ Vaccination has diminished the rate of hospital-acquired rotavirus infection in Australia as well.¹³ Follow-up studies on vaccinees in Finland have shown that the protective effect of RV5 is sustained for over 3 years following vaccination, and the reduction in hospitalizations and emergency department visits due to rotavirus infection has been over 90%.^{754,755} Of interest, in these and other postlicensure rotavirus vaccine studies, an unanticipated but clear-cut “herd immunity” effect has been observed.⁵⁷⁷ In a recent study from the United States, rotavirus vaccination was associated with substantial reductions in hospitalization rates and medical costs among unvaccinated individuals 5 to 24 years of age.⁴⁵⁷ That is to say, children who did not receive a rotavirus vaccination also experienced a decrease in rotavirus-associated morbidity following the introduction of these vaccines into the population. This population-level benefit is likely due to lowered transmission rates from vaccinated children, although the spread of vaccine virus from vaccinated to unvaccinated children is also possible in some cases. To date, no clear-cut difference in vaccine efficacy or safety at the population level has been observed between RV1 and RV5, and

there is not yet any compelling data at the population level to indicate that vaccine introduction alters the genotype distribution among circulating rotavirus strains.³⁵¹ Both RV1 and RV5 appear to be highly efficacious and safe in developed countries (Table 45.7).

Studies from middle- and low-income Latin America also show substantial decreases in hospitalizations in both Mexico and Nicaragua, although the effectiveness of RV5 in Nicaragua was less (58% against severe diarrhea) than in developed countries.^{567,609} Most striking are data from a study of RV1 in Mexico, which revealed a 41% decrease in diarrhea-related infant mortality in infants younger than 11 months of age that was clearly associated with vaccination.⁶²⁹ Follow-up studies in Latin America show that RV1 remained highly efficacious when co-administered with other childhood vaccines including oral polio.⁷³⁴

Morbidity and mortality due to rotavirus infections are higher in the poorest countries of Africa and Asia than in the developed world, and investigators predicted that a reproducible effect on severe morbidity would translate into a direct effect on mortality.²⁴³ In support of this prediction, in a recent report from Mexico, a middle-income country where RV1 is primarily used, diarrhea-related mortality, especially among younger children most likely to have been vaccinated, fell by over 40%.⁶²⁹ There is considerable evidence that a variety of orally administered vaccines, such as polio and some cholera vaccines, preform less well in very poor countries, such as India and Sub-Saharan Africa. Recent randomized controlled trials indicate that this is also true for both RV1 and RV5.^{20,467,818} The two current vaccines prevent severe rotavirus-associated gastroenteritis with an overall efficacy of over 90% in the United States and Western Europe, over 85% in regions of Asia where rotavirus results in low mortality, and 80% in Latin America. In contrast, studies of RV1 efficacy in South Africa and Malawi demonstrated significantly reduced efficacy of 77% and 49%, respectively.⁴⁶⁷ Similarly, a study of RV5 in Ghana, Kenya, and Mali revealed efficacy against severe diarrhea of only 39% but substantially higher overall efficacy during the first year of life (64%); efficacy rates varied by country, being highest in Kenya and lowest in Mali.²⁰ Finally, a double-blind, placebo-controlled trial of RV5 against

TABLE 45.7 Comparison of the Three Licensed Rotavirus Vaccines

	RotaTeq (RV5)	Rotarix (RV1)	RotaShield (RV4)
Manufacturer	Merck Vaccine Division	GlaxoSmithKline	Wyeth
Genetic backbone	Bovine rotavirus-WC3	Human rotavirus-89-12	Simian rotavirus-RRV
Composition	5 human; bovine reassortant	Single human rotavirus	4 human; simian reassortants
Human VP7/VP4 types	G1, 2, 3, and 4 and [P8]	G1 [P8]	G1, 2, 3, and 4
Dosage schedule	3 doses (2, 4, 6 months)	2 doses (6 weeks, 10+ weeks)	3 doses (2, 4, 6 months)
Administration	Oral	Oral	Oral
Presentation	Liquid	Liquid	Lyophilized-reconstituted
Protection against severe disease in: ^a			
Developed countries	85% (72-92)	95% (91-97) ^a	85% (69-91)
Low-income countries in Asia/Africa	48% (43-64)	61% (49-77)	NA
Virus shedding	21%	≥50%	50%
Rare intussusceptions	Yes	Yes	Yes

^aDifferent scoring systems, analyses, and populations were used so efficacy results are not directly comparable.

Adapted from Greenberg HB, Estes MK. Rotaviruses: from pathogenesis to vaccination. *Gastroenterology* 2009;136:1939–1951.

severe rotavirus gastroenteritis in developing countries of Asia (rural Bangladesh and urban Vietnam) demonstrated an overall efficacy rate of 48%, with rates in Bangladesh being lower (43%) than those in Vietnam (64%).⁸¹⁸

In summary, large randomized studies have confirmed that overall efficacy of the two currently licensed live, attenuated rotavirus vaccines (RV1 and RV5) is significantly lower in the poorer countries of Asia and Africa than it is in high- or middle-income countries. That said, analysis of the impact of rotavirus vaccination on the burden of rotavirus disease by the WHO and others indicates that the current two licensed rotavirus vaccines will actually have their greatest impact on morbidity and likely mortality in the poorest countries because, despite their lower efficacy in these settings, the burden of disease is so much higher. Because of this substantial beneficial effect, in 2009 the WHO's Strategic Advisory Group of Experts recommended that health authorities in all nations routinely vaccinate young children against rotavirus.

The widespread use of RV1 and RV5 allows the opportunity to better understand the safety profile of these two vaccines. Both vaccines are shed in appreciable amounts following vaccination (with RV1 shed at higher levels than RV5), but, to date, no adverse effects have been associated with vaccine transmission.⁸⁰⁴ As mentioned earlier, in the initial, very large safety trials, serious reactogenicity was not observed and there was no association of either RV1 or RV5 with intussusception. However, despite the sizes of these phase III safety studies, they were underpowered to detect very rare safety problems and would not have detected adverse events occurring at rates below 1 in 25,000 or so. Recent population-based studies from Mexico, Brazil, and Australia now are providing new data that indicate very rare temporal associations of both RV1 and RV5 (as was the case with RV4 vaccine, see earlier) with intussusception.^{92,568} The rates of vaccine-associated intussusception appear to be very low, less than 1 in 50,000, and it seems clear that the benefits of these two vaccines substantially exceed the risks based on the data currently available.³⁰¹

Several other potential safety issues have also arisen during the postlicensure period. Deep sequencing analysis of the RV1 vaccine revealed that it was heavily contaminated with a previously undetected infectious porcine circovirus, likely introduced from a porcine trypsin additive used in manufacture.⁷⁶⁴ The FDA evaluated the risks and benefits associated with this adventitious agent contamination and recommended that the real benefits of the vaccine outweighed the potential risks and that the vaccine should remain available for use but that the manufacturer should work expeditiously to derive new seed stock that was not contaminated. In addition, recent reports demonstrate that severely immunocompromised infants are at risk for vaccine-acquired chronic infection and illness, despite the attenuated nature of the rotavirus vaccines,⁵⁶⁹ and this led to a change in the vaccine label to exclude administration to children with SCID. In summary, in the past 5 years, two highly safe and effective live, attenuated rotavirus vaccines have been widely introduced. Both appear to be associated with very rare safety risks, but both are highly beneficial. At the time of this review, both of the new vaccines were relatively expensive and the costs exceed the ability of many countries to purchase and deliver these vaccines widely in a sustainable manner. For this reason, the ready availability of less expensive, safe, and effective vaccines would be desirable.

Other Live, Attenuated Rotavirus Vaccines in Clinical Development

The bovine rotavirus UK strain constitutes the backbone of a tetravalent human-bovine rotavirus reassortant vaccine candidate, composed of individual human-bovine rotavirus reassortants with VP7 specificity for G1, G2, G3, and G4 in a background of 10 bovine rotavirus genes.^{507,508} Additional G-type UK monoreassortants are also available for inclusion in a vaccine if needed.³⁹⁹ Each component alone was nonreactogenic and immunogenic in clinical trials.¹⁴¹ The four reassortant strains were combined into a tetravalent formulation that also proved to be safe and immunogenic.¹⁴⁰ In an efficacy trial in Finland, the UK-based tetravalent vaccine had a protective efficacy of more than 80% against severe rotavirus diarrhea.⁷⁵⁷ The UK-based reassortant vaccine has now been licensed by the National Institutes of Health to several vaccine manufacturers in Brazil, China, and India and is currently undergoing development and clinical testing in those countries.¹⁸¹ If proven to be safe and efficacious, it is hoped that manufacture of this vaccine in less developed countries will lead to an affordable rotavirus vaccine.

Another approach to rotavirus immunoprophylaxis involves the use of live, orally administered neonatal human rotavirus strains that appear to be naturally attenuated. The impetus for evaluating neonatal strains came from the early observations that neonates who experienced subclinical rotavirus infections in Australian or Indian nurseries during the first 14 days of life were protected against clinically significant rotavirus diarrhea for up to 3 years.^{51,57} Clinical studies with neonatal strain RV3 (G3, P2A), isolated from the Australian nursery study described earlier, are under way to determine if the vaccine candidate is immunogenic, safe, and efficacious.^{36,37} In addition, a large phase III randomized, double-blind, placebo-controlled clinical trial of an asymptomatic neonatal nursery rotavirus strain isolated in India is now under way. This strain (116E, G9P8[11]) is a naturally occurring human-bovine rotavirus reassortant originally isolated in New Delhi.²⁷⁶ The 116E strain has 10 human rotavirus genes and a single bovine rotavirus gene encoding VP4. Preliminary phase I and II clinical trials indicate that it is attenuated but highly immunogenic in Indian infants. The 116E vaccine, if safe and effective, will be available at a substantially reduced cost compared to the two currently licensed vaccines.

Finally, the RRV-based tetravalent RotaShield vaccine (RV4) has been reformulated and is currently being tested in phase III safety and efficacy trials in Africa, premised on the ideas that it appears to be somewhat more immunogenic than either RV1 or RV5 and this increased immunogenicity might translate into improved efficacy in very poor countries. This plan is coupled with the rationale that if RV4 is given to newborns or children younger than 2 months of age at the time of the first dose, risks of intussusception will be very low.

Other Approaches to Vaccination

Due to the relatively poor efficacies of RV1 and RV5 in very poor countries of Africa and Asia, other strategies for rotavirus immunization are being explored. Among the most actively pursued approaches is the use of inactivated virus or recombinant virus-like particles administered parenterally.³⁷² Several types of animal studies in pigs and primates support the potential

of these approaches to induce protective immunity, and studies in primates have shown that systemically administered, passively transferred serum antibodies can protect from infectious rotavirus challenge.⁷⁸⁷ Other much less thoroughly examined approaches include the use of (a) synthetic viral proteins, (b) viral proteins expressed from cloned rotavirus cDNA, (c) synthetic peptides, and (d) DNA vaccines.^{87,144,334,358,778} None of these alternative strategies have yet advanced to the stage of initial testing in people.

Passive Immunization

Passive immunization with some form of rotavirus-enriched antibody preparation has been shown to be effective in preventing or modifying rotavirus illness in animals.^{200,326,666,787} Similar studies have now been carried out in infants and young children, with promising results in most, but not all, instances.^{35,88,170,201,202,316} Various sources of passively administered rotavirus antibodies (e.g., eggs from immunized hens, or milk formula containing bovine milk immunoglobulin from milk of cows hyperimmunized with human rotaviruses) have been considered.^{170,810,811} However, except in very special circumstances, such as in immunocompromised individuals with severe or chronic rotavirus infection, passive immunization is simply not currently practical for protection against rotavirus illness due to cost and lack of commercially available licensed product.

PERSPECTIVES

Rotavirus disease has become vaccine preventable with clear and substantial evidence of efficacy for children in developed and developing countries and reductions of mortality in children in developing countries. This is an exciting achievement, yet other questions remain to be answered regarding vaccines: Can the efficacy of the current oral vaccines be improved in children in some developing countries based on understanding why such children do not respond with high rates of induced protective immunity? Is this due to malnutrition, intestinal microbiota, frequent infection with other intestinal pathogens, or other health factors of the children, or to different circulating rotavirus strains that are not part of the current vaccines? Will worldwide vaccination induce changes in the epidemiology of circulating virus strains? Will epidemiology studies be able to show that vaccination reduces rare childhood diseases, such as biliary atresia, that might be associated with rotavirus infections but where causation has been difficult to prove in children? Can a correlate of protection be identified to facilitate the future development of third-generation vaccines?

Even with successful vaccines, rotaviruses will continue to serve as very useful models to understand mucosal virus–cell interactions. The interactions of viral and cellular proteins that influence virus entry into cells, trigger epithelial cell responses, and modulate function of the differentiated epithelial cells or neighboring cells in the complex architecture of the intestine remain to be understood. This will require new studies of virus pathogenesis *in vivo*, and such studies will require multidisciplinary efforts to understand fully the complex biochemical and physiologic consequences of infection. Rotaviruses also provide a prototypical infection for the study of the local intestinal innate and acquired immune response. Some questions to be asked include the following: Why do rotavirus infections

cause minimal intestinal inflammation? How do rotaviruses escape the intestine and cause extraintestinal infections? Do such infections result in currently unrecognized disease in a subset of individuals with specific genetic properties? What is the basis for host-range and organ-specific replication restriction? What factors govern the development of homotypic versus heterotypic humoral immunity? Why is the circulating T-cell response so small following rotavirus infection? What role does innate immunity play in determining the clinical outcome of rotavirus infection in people? Continued analysis of cellular responses (both epithelial and immune) by using microarray and proteomics analyses will help define pathways of cellular signaling that influence the outcome of infection as well as cellular genes important for replication. More studies on rotaviruses that represent most human and animal rotavirus strains that infect cells in a neuraminidase-resistant fashion and that replicate less efficiently in cultured cells clearly are needed to understand how these viruses differ from the well-studied neuraminidase-sensitive viruses. Will study of these viruses discover that they have other unexpected receptors or unusual properties that affect their stability or transmission? The first reports of success with reverse genetics systems for the rotaviruses should facilitate future probing of viral gene function, which is especially needed to fully understand pathogenesis. Achieving a more efficient and tractable reverse genetics system may require more knowledge about the unique processes by which rotaviruses inhibit host cell translation, enhance virus-specific RNA replication, and achieve genome encapsidation that may be linked and compartmentalized within the cytoplasm of cells. The application of new techniques in cell biology to understand the structural and biochemical basis of the unusual processes of rotavirus entry into, and exit from, cells can be expected to unravel new mechanisms of intracellular protein and vesicle trafficking. Structural knowledge of rotavirus and its proteins should help lead to new methods and inhibitors to interrupt virus transmission, prevent virus replication, and treat disease.

Perspective

parts of the world, including Palestine, Turkey, Israel, Pakistan, and the Indian subcontinent.^{27,66}

In the late 18th century, BT disease was observed in domestic animals as well as in wild ruminants (e.g., Blesbuck, white-tailed deer, elk, and pronghorn antelope). As with AHS, BT disease was confined to Africa for many decades. Distinctive lesions in the mouths of the infected animals with a dark blue tongue were the characteristic symptoms. A detailed description of the disease was first published in 1905,¹¹² when it was named *malarial catarrhal fever*,²⁶ and Theiler demonstrated that the agent was a filterable virus.¹²⁵ The first confirmed outbreak outside of Africa occurred in Cyprus in 1924, followed by outbreaks in 1943 to 1944 when about 2,500 sheep died with a mortality rate reaching 70%. In the United States, BT disease in sheep was first recognized in 1948, and in 1956 a major epizootic began in Portugal and extended into Spain. Outbreaks of BT disease in the Middle East, Southeast Asia, southern Europe, and the United States in the early 1940s and 1950s led to its description as an *emerging disease*.⁵² Virus isolates, of 26 different serotypes, have been made in tropical, semitropical, and temperate zones of the world, including North and South America, Australia, southern Europe, Israel, Africa, and Southeast Asia. In 1998, significant outbreaks of BT occurred in Europe, initially in Greece and then in many other Mediterranean countries, causing the death of over a million sheep by 2005.⁹⁶ In 2006 and 2007, BTV emerged in North-western Europe eventually expanding into the United Kingdom, Denmark, and the Czech Republic. An important factor in the distribution of BTV worldwide is the availability of suitable vectors, usually biting midges (gnats) of the *Culicoides* species.

HISTORY

Two important orbivirus diseases are African horse sickness (AHS) and Bluetongue (BT) disease of sheep and cattle, both recognized first on the African continent.^{47,124} The first major outbreak of AHS was observed in 1719, when approximately 1,700 animals died and the most significant outbreak occurred in 1854 to 1855, affecting some 70,000 horses. AHS mainly appeared in years of unusually high rainfall and warm weather, and it was speculated that insect vectors were involved in spreading of the disease. Only in 1900 was it demonstrated that AHS was caused by a virus, when M'Fadyean succeeded in transmitting the disease by a bacteria-free filtrate from an infected animal to a healthy one.⁸⁸ The major vertebrate reservoir for the virus was believed to be zebra.³ To date, AHS virus occurs in multiple serotypes (AHSV-1 to 9) and is endemic in eastern and central Africa and many parts of sub-Saharan Africa. From 1943 onward, AHS outbreaks have been reported in different

CLASSIFICATION

The *Orbivirus* genus is one of 15 genera within the *Reoviridae* family, which includes vertebrate, arthropod, and plant pathogens. Despite a basic similarity, orbiviruses differ greatly in their structure, physicochemical properties, replication cycle, pathogenesis, and epidemiology. Unlike the reoviruses and rotaviruses, orbiviruses are arthropod-borne, and 22 serogroups or virus species of orbiviruses are distinguished in addition to several unclassified isolates.⁸⁷ Within each serogroup, multiple serotypes are differentiated by neutralization tests. Different orbiviruses infect a wide range of vertebrate hosts, including ruminants (domesticated and wild), equids (domesticated and wild), rodents, bats, marsupials, birds, sloths, and primates, including humans. The orbivirus serogroups, serotypes, principal vectors, and main hosts are listed in e-Table 46.1 with their assigned abbreviations.⁸⁷

VIRION STRUCTURE

Orbiviruses are nonenveloped, icosahedral particles containing segmented, double-stranded RNA (dsRNA) genomes. BTV, the prototype of the genus, is the main subject of this chapter. BTV virions (550S) are architecturally complex structures composed of seven discrete proteins that are organized into two concentric shells, the inner and outer capsids¹³⁸ (Fig. 46.1). The virion proteins encapsidate a genome of 10 dsRNA segments that can be divided into three different size classes (large, medium, and small). Unlike reovirus and rotavirus particles, mature BTV particles are relatively fragile, and the infectivity of BTV is easily lost in mildly acidic conditions. The outer capsid of BTV consists of two major proteins, VP2 and VP5, which are removed shortly after infection, to yield a transcriptionally active core (470S) particle (Fig. 46.1) which, in contrast to virions, is fairly robust. Cores contain two major proteins (VP7 and VP3), three minor proteins (VP1, VP4, and VP6), and the dsRNA genome.¹³⁸ They may be further uncoated to form sub-core particles (390S) that lack VP7. Cores can also be derived from virions *in vitro* by removal of the outer capsid.^{56,134}

Virion Particle and Outer Capsid

Early electron microscopy (EM) visualizations were of characteristically fuzzy particles, suggesting BTV is highly sensitive to preparation conditions.²⁴ However, cryo-electron microscopy (cryo-EM) and image reconstruction of BTV particles revealed an icosahedral symmetry of the virions with a diameter of ~880 Å and an accurate positioning of VP2 and VP5 proteins in relation to each other and to the underlying core surface.^{49,91} The images revealed a total of 60 triskelion spike-like structures formed by VP2 trimers and 120 globular structures of VP5 trimers, both of which attach to the underlying core surface layer independently of each other. A recent 7 Å resolution cryo-EM structure of virion (Fig. 46.2) further identified the secondary structural elements and the topological arrangement of these two proteins.¹⁴⁴ Each VP2 monomer has two distinct domains, a tip domain and a lower region, three of which form a hub domain at the base of the triskelion spike. The top of the VP2 tip domain is rich in β sheets and projects upward from the surface of the virion. The hub has a distinct β -barrel fold (Fig. 46.2C) and each monomer contains a sialic acid (SA) binding pocket (Fig. 46.2D).

FIGURE 46.1. Bluetongue virus particles and proteins. **A:** Schematic diagram of bluetongue virus (BTV) showing the positions and structural organization of BTV components. **B:** Electron micrographs of negatively stained purified BTV particles and cores.

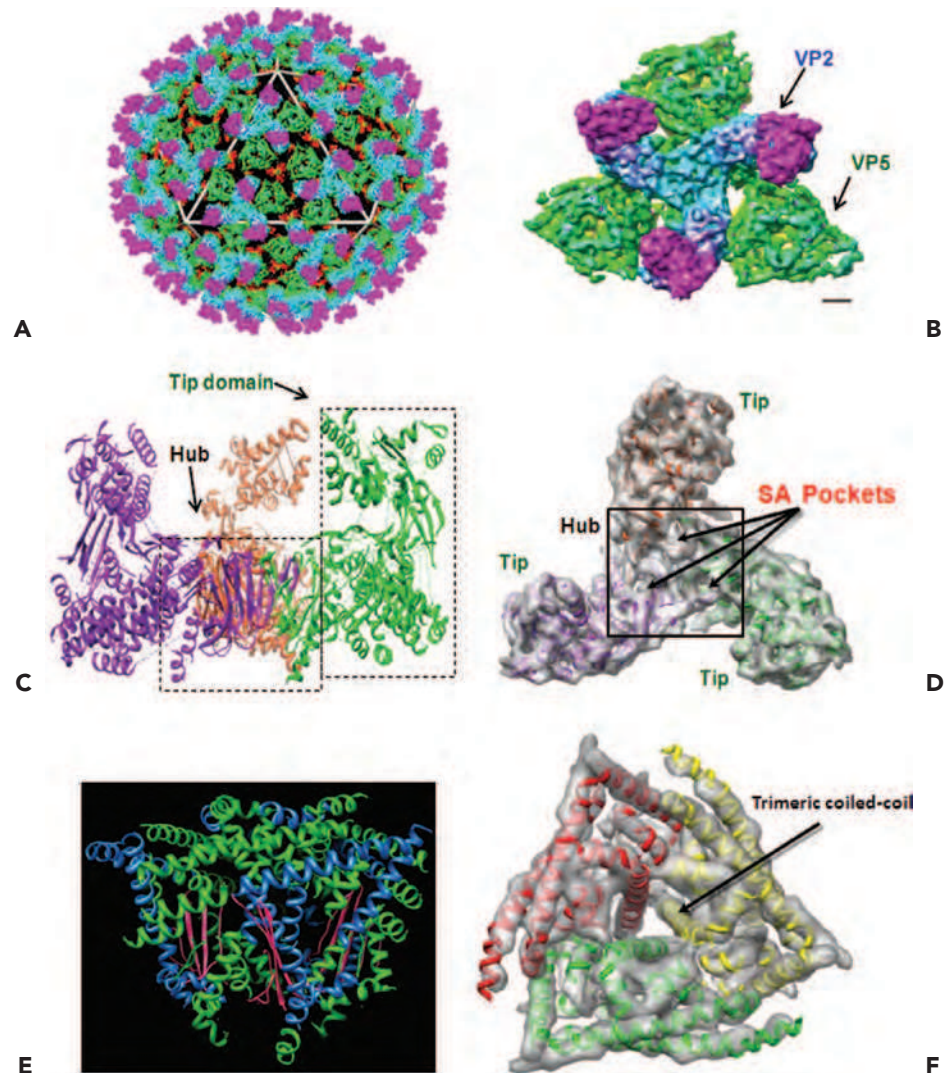

FIGURE 46.2. Cryo-electron microscopy (cryo-EM) structure of complete bluetongue virus 1 (BTV-1) particle at 7 Å resolution. **A:** Surface representation of whole particle showing VP2 (magenta/cyan) and VP5 (green) of outer capsid, and VP7 (red) of core. **B:** A cut-off section showing the arrangement of VP2 and VP5 trimers. **C:** VP2 triskelion formed by three VP2 monomers, each consisting of a tip domain and a part of the hub domain. **D:** A putative sialic acid-binding pocket is located at the hub domain. **E:** Side view of a VP5 trimer as a helical globular complex; the amphipathic helices (blue), nonamphipathic helices (green), and the single B-sheet (red). **F:** Top view of VP5 with an embedded ribbon model showing the central coiled-coil helix bundle.

In contrast to VP2, the VP5 trimer is globular, very rich in helices, and possesses only one β sheet (Fig. 46.2E). Five distinct amphipathic α -helical regions lie on the exterior surface of the protein, including an N-terminal α helical region that is positioned on the exposed surface of VP5.¹⁴⁴ A cluster of three copies of one amphipathic helix are well positioned to expose their hydrophobic undersides to the endosomal membrane (Fig. 46.2E). Other amphipathic helices are similarly located on the exposed surface, where they may mimic the arrangement seen in other fusion proteins such as the fusion protein of the enveloped HIV (Fig. 46.2F). The gaps among the VP2 triskelions are filled by three VP5 trimers. Density maps suggest that VP5 trimers interact very weakly with the VP2 hub domains and with the underlying core surface, but both the VP2 tip and hub domains connect to their underlying VP7 trimers by stronger forces.

Core Particle and Proteins

Core particles derived from purified virus *in vitro* are stable and have been studied extensively at the structural level, initially by cryo-EM (at various resolutions between 22 Å and 40 Å) and subsequently by establishing a 3.6-Å atomic structure from crystals, which has revealed four distinct features.

Surface Layer of the Core and VP7 Trimers

The core surface has a diameter of 73 nm with an icosahedral symmetry triangulation number of 13 ($T = 13$) in a left-handed configuration. The surface layer of VP7 trimers (appear as prominent triangular shapes) occupies the space between radii of 260 Å and 345 Å. The trimers are arranged around 132 distinctive channels as six-member rings, with five-member rings at the vertices (Fig. 46.3A). A total of 780 VP7 (38 kD) molecules per particle form 260 quasi-equivalent trimers the protomeric unit (P, Q, R, S, T), which can be seen clearly. Aqueous channels surrounded by these trimers are about 8 nm wide and 8 nm deep. Based on their location with respect to the icosahedral symmetry axes, they can be grouped into three types; type I channels run along the icosahedral fivefold axes, type II channels surround the fivefold axes, and type III channels are located around the icosahedral threefold axes. The arrangement of each monomer within the VP7 trimer was shown by x-ray crystallography.^{4,41} Each monomer (349 amino acids for BTV-10) consists of two distinct domains, “upper” and “lower,” which are twisted in such a way that the top domain of one monomer rests upon the lower domain of another (Fig. 46.3B). The smaller upper domain of VP7 forms the “head

FIGURE 46.3. Three-dimensional structures of bluetongue virus (BTV) core and VP7 protein. **A:** Surface representations of the three-dimensional (3D) cryo-electron microscopy (cryo-EM) structures of BTV-10 core (700 Å in diameter) viewed along the icosahedral threefold axis showing the trimers of VP7 (in blue). The five quasi-equivalent trimers (P, Q, R, S, and T) and the locations of channels II and III are marked. **B:** The trimer image of the VP7 atomic structure solved at 2.8 Å resolution. Two domains of the molecule, the carboxyl and amino termini, are indicated. The view is shown from the side. Note the flat base of the trimer lies in a horizontal plane in this view.

region” of the trimer, which appears as a “knobbly” projection on the surface of the core and contains the central one-third of the polypeptide chain of the molecule (amino acids [aa] 121–249) folded into an anti-parallel β -sandwich. Two other x-ray structures of upper VP7 domains, one from BTV-10 (aa 123–253) and one from AHSV type 4, also revealed a similar structural arrangement. The lower, broader domain of the monomer is composed of nine α -helices and long extended loops, and is formed by both the N (aa 1–120) and the C (aa 250–349) termini of the molecule. A single lysine residue, prone to proteolysis, is situated at the junction between the two domains, and its mutation has a deleterious effect on core assembly.⁶⁹ A low resolution (5.4 Å) VP7 structure indicated a very different orientation of the helical lower domain from that of the high-resolution structure, suggesting an “unwound” or “open” form compared to the tightly packed helices found in the high-resolution form.⁴ These two very different structures indicate that VP7 has the potential for internal flexibility in the lower domain and suggest that substantial conformational change in VP7 occurs at some stage in the viral life cycle.

X-ray crystallographic structures for core particles of two different BTV serotypes (BTV-1 and BTV-10) have confirmed the precise organization of the 260 VP7 trimers⁴² (Fig. 46.4A). The channels, or “pores,” are small (7 Å diameter) at the icosahedral threefold axes (class III) and slightly larger (9 Å diameter) at the fivefold axes (class I), where they act as “portals” to release the newly synthesized transcripts. Although the “T” trimers of VP7 sit tightly on the pores at the threefold axes, the “P” trimers are located loosely above the pores at the fivefold axes. At the interface between VP7 and VP3, the VP7 trimer layer is principally formed by side-to-side packing of

short hydrophobic side chains, whereas interaction with the VP3 underneath layer is extensive and relatively tight. The lower domains of VP7 pack down against six corners of each VP3 molecule such that 12 monomers of VP7 (4 trimers) are in direct association with VP3 molecules. The thirteenth monomer of VP7 (organized in the icosahedron $T = 13$) is not directly in contact with a VP3 molecule, but is slightly raised and is in contact with monomers of adjacent trimers.

Arrangement of VP3 Molecules in the Inner Layer

The inner core layer, beneath the VP7 layer, is made up solely of VP3 proteins and occupies the space between radii 230 and 260 Å. Unlike the VP7 layer, the VP3 layer appears as an almost spherical structure as revealed by high-resolution x-ray structure of the cores.^{42,43,48,94}

Sixty dimers of VP3 (103 kD) serve as the unit building block to form the disc-shaped VP3 shell of 59 nm diameter and with an internal diameter of 38 nm that contains both the genome, as well as the minor core proteins.⁴² The 120 molecules of the VP3 shell are organized as an icosahedral lattice with $T = 2$ symmetry (Fig. 46.4B) and are arranged as two sets (A and B) of 60 subunits (Fig. 46.4C). Five of the “A” group of molecules are arranged as a five-pointed star around each fivefold axis, and five “B” group molecules are positioned, one between each of the points of the star, but at a further distance from the fivefold axis to produce a decamer. Such icosahedral organization of the inner shell is shared by all members of *Reoviridae* and other viruses with segmented dsRNA genomes. The inner surface of the VP3 shell has relatively few charged residues and has a series of shallow grooves.

FIGURE 46.4. The x-ray structure of the blue tongue virus 1 (BTV-1) core. **A:** Surface of the core structure showing the arrangement of 260 trimers. The structurally equivalent trimers have been given the same color. **B:** The structure of the VP3 layer showing the arrangement of 120 copies of two conformationally distinct types of VP3 molecules, “A” shown in green and “B” shown in red. Sixty copies of each of the two molecules together form 12 decamers that are linked together forming a thin protein shell. The icosahedral fivefold, threefold, and twofold symmetry axes are indicated. **C:** Structures of two types of VP3 molecule, A (left) and B (right), as observed in the BTV-1 core. The molecules are very similar in overall shape of thin triangular plates, with slight differences in conformation.

Structural Arrangement of Internal Minor Proteins

A clear density internal to the VP3 layer, in both the virion and the core cryo-EM reconstructions and in the x-ray structure, was assigned to the internal minor proteins (VP1, VP4, and VP6). In the absence of the viral genome, cryo-EM reconstruction shows the complex as a flower-shaped density directly beneath the icosahedral fivefold axes and attached to the underside of the VP3 layer⁹¹ (Fig. 46.5). It is not clear whether the VP6 protein is complexed with VP1 and VP4 at the fivefold vertices of the core; from *in vitro* studies, it can be deduced that the VP6 is tightly associated with the genomic RNA.

A modeled structure of VP1 has revealed a typical RNA dependent RNA polymerase (RdRp) organization with a distinct central polymerase domain (PD), an N-terminal domain (NTD), and a C-terminal (CTD) domain similar to that of Reovirus and rotavirus.¹⁴⁰ The model was supported by mutagenesis combined with dissection of biological activity of each

domain, and it is likely that all *Reoviridae* polymerases share similar structural organization.

An atomic structure is available for VP4, the capping enzyme of the virus.^{80,97,119} It shows an elongated morphology composed of four domains, which includes an N-terminal kinase-like domain (KL); a center methyltransferase-1 domain (N7MT) and O2-methyltransferase-2 domain (O2MT), and a C-terminal Guanylyltransferase (GTase) domain (GT) (Fig. 46.6). The 2'-O-MT structure is similar to the catalytic domains of class I S-Adenosyl L-methionine (SAM) SAM-dependent methyltransferases and in particular to vaccinia virus VP39. A Lysine Aspartic Lysine Glutamic (KDKE) tetrad in the active site seems to be characteristic of RNA2'-O-MTases. The N-terminal 108 residues of VP4 show a kinase-like fold (KL domain), and is the least conserved domain among the capping enzymes of different orbivirus species, whereas the GT domain is the most highly conserved region of VP4 between different orbivirus species. Functional analyses indicate that

FIGURE 46.5. Organization of internal proteins (transcription complex) and RNA genome.

A flower-shaped density features (red) attached to the inside surface of VP3 (green) at all the fivefold axes is clearly seen. **B:** Conical cut-away from the reconstruction providing close-up views of the flower-shaped structure (red) and its interaction with the VP3 layer (green).

FIGURE 46.6. Cartoon representation of the structure of the VP4 molecule: Ribbon diagram of the VP4 structure with enzymatic domains coloured: guanylyl transferase (GT, blue), kinase-like guk domain (KL, orange), guanine-N7-methyltransferase (N7MT, green), and (nucleoside-2'-O)-methyltransferase (2'OMT, purple) domain.

catalytic residues of the GT lie with the 98 aa of the C-terminus where a number of conserved lysine and histidine residues could form the guanine adduct required for GTase activity.

RNA Genome Seen in X-ray Structure of the Core

The electron density in the x-ray structure of the core exhibited features consistent with layers of highly ordered RNA.⁴⁰ Approximately 80% of the genome can be modeled as four concentric layers that have center-to-center spacing between RNA strands of 26 to 30 Å. Grooves in the inner surface of the VP3 shell form a spiral around the fivefold axis with which the dsRNA layers appear to interact. The topography of the RNA molecules is uncertain, as the density detected in the inner layers of RNA gets progressively weaker, although each layer maintains an overall spiral organization.⁴⁰

GENOME STRUCTURE AND ORGANIZATION

The complete sequences of all 10 dsRNA segments were initially determined for BTV-10³⁷ and subsequently for a number of BTV serotypes as well as for many other orbiviruses (see review, 87,108). For BTV-10, the sizes of the RNA segments range from 3,954 (segment 1) to 822 base pairs (bp) (segment 10) (e-Fig. 46.1) and the total genome is 19,220 bp long³⁷ (Table 46.1). The 10 dsRNA segments of BTV have conserved terminal sequences with conserved 5' (8 nucleotides) and 3' (6 nucleotides) termini.⁹⁹ The 5' terminus of the coding strand of each duplex is capped and methylated, as are the BTV messenger RNA (mRNA) transcripts.

TABLE 46.1 Bluetongue Virus (BTV-10) Coding Assignments

Segment No.	Protein	No. of amino acids	Estimate No. molecules per virion	Location in virion particle (VP1–VP7)	Function
1	VP1	1,302	12	Inner core	RNA polymerase
2	VP2	956	180	Outer shell (spike)	Receptor binding, virus entry, hemagglutinin, type-specific, neutralization
3	VP3	901	120	Subcore layer (scaffold)	Forms scaffold for VP7 trimers, interacts with transcription complex and genomic RNA
4	VP4	654	~24	Inner core	Capping enzymes-guanylyltransferase, methyltransferases 1 and 2, RNA 5' triphosphatase, inorganic pyrophosphatase, NTPase
5	VP5	526	360	Outer shell (globular)	Virus penetration, fusogenic
6	NS1	552	High level	Nonstructural	Forms tubules, binds BTV transcripts and enhances protein synthesis
7	VP7	349	780	Core surface layer	Forms surface of core, responsible for core entry into insect cells
8	NS2	357	NA	Nonstructural	Phosphorylated, recruits BTV single-stranded RNA (ssRNA), forms cytoplasmic inclusion bodies, site for core assembly
9	VP6	328	60–72	Inner core	Viral helicase, adenosine triphosphatase (ATPase), form hexamer in presence of BTV RNA
10	NSP4	77–79	NA	Nonstructural	Interact with animal host
	NS3	229	NA	Nonstructural	Glycoproteins, membrane proteins, interact with host
	NS3A	216	Low level		membrane proteins calpactin, Tsg101 and outer capsid proteins, aids virus trafficking and release. NS3A is essential for virus maturation in vector insect cells

Apart from segment 1, the first AUG initiation codon in the mRNA strand of each segment initiates a single open reading frame (ORF). There are two methionine codons in the same reading frame in the S10 RNA sequence, coding for two related proteins: NS3 and NS3A.^{34,85} Recently an additional small non-structural protein has been identified, NSP4 encoded by S9, which also encodes the structured protein VP6.¹⁴⁵ The encoded structural proteins are numbered VP1 to VP7 in the order of their migration on sodium dodecyl sulfate (SDS)–polyacrylamide gels. In addition to the seven structural proteins in virion particles, four nonstructural proteins (NS1, NS2, NS3, and NS3A) are synthesized in infected cells.¹⁰⁸

MOLECULAR GENETICS

As early as 1981, the genetic diversity of the different BTV genome segments was identified by RNA oligonucleotide fingerprint analyses of field samples, and both genetic drift and shift were shown to contribute to BTV evolution.¹⁰⁸ In some segments, variability was clearly linked to serotype (e.g., segments 2 and 5 encoding outer capsid proteins VP2 and VP5). In addition, oligonucleotide fingerprinting revealed that genome segment reassortment occurs readily between different BTV serotypes and within other orbivirus serogroups, but not between viruses belonging to different groups.^{39,107} Partly as a result of these data, individual orbivirus serogroups are now recognized as distinct virus species.⁸⁷

Early molecular hybridization studies confirmed that genome segments 2 and 5 exhibited little or no cross-hybridization between serotypes, whereas the other eight RNA segments consistently showed some level of relatedness. Segments 1, 3, 4, 6, and 8 are relatively conserved, whereas segments 7 and 10 vary somewhat. Apart from segment 10 of AHSV, which appears to be even more variable than that of BTV, similar results have been obtained for AHSV.^{18,135}

Recently, an extensive phylogenetic analysis of segments 2 and 5 from >300 different BTV isolates has shown that the

nucleotide sequence of segment 2 varies from 29% to 59% between different serotypes.^{76,101} Based on this analysis, 26 serotypes were identified forming 10 distinct groups based on the fact that some serotypes are more related than others^{74,76} (e-Fig. 46.2A). Isolates within each serotype can also be separated into two major geographical groups, *group E*, from the East (India, Indonesia, China, Australia), and *group W*, from the West (Africa and North and South America).⁷⁴ Far less variation occurs in segment 5, which encodes VP5, although it too shows some correlation with serotypes.⁷⁶ A close genetic relationship has also been demonstrated among BTV, EHDV, and AHSV, three *Culicoides* transmitted Orbiviruses. Segments encoding the core proteins, for example, VP3, are the most conserved, whereas VP2 is the most variable^{60,102,141} (e-Fig. 46.2B). Despite as little as 17% to 23% identity, however, the VP2 protein of the three orbiviruses has a similar predicted secondary structure. Unlike VP2, the other outer capsid protein VP5 is more conserved among the three viruses, clearly indicating these viruses share strong phylogenetic relationships.

STAGES OF VIRUS REPLICATION

The basic features of replication cycle of orbiviruses are similar to those of reoviruses and rotaviruses. Unlike reoviruses or rotaviruses, however, orbiviruses multiply in arthropod as well as in vertebrate hosts, and thus some stages of orbivirus replication and morphogenesis are unique. The overall information available on the BTV replication cycle and assembly is summarized in a schematic diagram (Fig. 46.7).

Virus Entry

Of the two outer capsid proteins, the larger VP2 (110 kD) is the receptor binding protein responsible for eliciting neutralizing antibodies and also has hemagglutination activity. Furthermore, recent structural data revealed that the VP2 trimer has two putative ligand-binding domains, one at the tip of the monomer and the other, an SA-binding pocket, at the base

FIGURE 46.7. Replication cycle of bluetongue virus (BTV). Schematic diagram of an orbivirus replication cycle (deduced from bluetongue virus data).

of each trimer that binds type 2 oligosaccharide structures (Gal α 14GlcNAc α 13) in glycan arrays.^{9,144} In BTV VP2 the SA binding domain is about 40 Å inward from the outer end of the tip domain, a distance well within the range of lengths of chains of sugars on glycoproteins.¹⁴⁴ Because it is known that BTV particles agglutinate erythrocytes of ruminants²⁰ and VP2 alone is responsible for this activity,⁴⁶ it can be postulated that SA binding may promote adsorption of the virus onto the surface of erythrocytes, thereby increasing the probability of ingestion by the blood-feeding *Culicoides* vector.

The attachment of VP2 leads to receptor-mediated endocytosis of virions in clathrin-coated vesicles (Fig. 46.7). Clathrin is subsequently lost, and large endocytic vesicles are formed. Both VP2 and VP5 proteins can be identified within the early endosome where either one or both proteins are degraded.^{22,31,45} Compounds that raise the lysosomal or endosomal pH (e.g., ammonium chloride) prevent endocytosis of virus particle and the subsequent release of the uncoated cores into the cytoplasm.³⁰

As discussed above, VP5 shares certain structural features with the fusion proteins of enveloped viruses, consistent with membrane penetration activity.¹⁴⁴ Peptides representing the two amino terminal amphipathic helices of VP5 cause leakiness of the membrane, and the full-length protein triggers strong syncytia and multinuclear cells when localized to the plasma membrane and treated with low pH^{31,46} (Fig. 46.8). Therefore, VP5 functionally substitutes for a typical viral fusion protein, although it does not require proteolytic activation to render it fully functional as in the case of reovirus protein.

Combining the available structural and biochemical data, a plausible hypothesis would be that upon receptor binding and entry VP2 trimers undergo rearrangement or degradation, allowing the exposure of VP5 trimers and thereby allowing the VP5 amphipathic helices to freely interact with membranes and initiate the permeabilization process.

In summary, VP2 makes an initial contact with the mammalian host cell and VP5 mediates the penetration of the host cell membrane by destabilizing the endosomal membrane. Core particles lacking both VP2 and VP5 proteins are released into the cytoplasm from the endosomal vesicles. In contrast to mammalian host, BTV cores lacking VP2 and VP5 are infectious for invertebrate cells⁸⁶ with the Arginine Glycine Aspartic (RGD) motif of VP7 involved in entry into cells of *Culicoides* species.¹²²

Transcription and Replication

After cell entry, the outer capsid is removed to release a transcriptionally active core particle, which provides a compartment within which the 10 genome segments are repeatedly transcribed by the core-associated enzymes VP1, VP4, and VP6.^{134,139} Ten capped nonpolyadenylated mRNAs are synthesized from the 10 genome segments and are released from the core particle into the host cell cytoplasm where they act as templates both for translation and for negative-strand viral RNA synthesis to generate genomic dsRNAs.^{85,133,134} Transfection of mammalian cells with *in vitro* BTV transcripts also leads to generation of viral proteins and infectious virus particles, as demonstrated by the passage of infectivity in Baby Hamster Kidney cells (BHK) cells.¹² These findings have allowed the development of a helper virus-independent reverse genetics system for BTV and other orbiviruses and for the generation of targeted mutant viruses.^{12,81}

When intact cores isolated from virus particles are activated *in vitro* in the presence of magnesium ions and NTP substrates, distinct conformational changes can be seen around the fivefold axis.⁴⁰ This is interpreted as an outward movement of VP3 and VP7, allowing opening of a pore in the VP3 layer at the fivefold axes through which the mRNAs are extruded. The structural integrity of the core particle appears to be essential for efficient transcriptional activity *in vivo*, but it has been possible to use *in vitro* assays with the three minor proteins of the core to delineate the specific roles of each (see review in 103; Fig. 46.9).

FIGURE 46.8. Fusion activity of VP5: *Spodoptera fugiperda* cells infected for 48 hours with a recombinant baculovirus expressing a chimeric VP5 that is flanked by the baculovirus gp64 signal peptide and the Vesicular Stomatitis Virus (VSV) G anchor domain. Note the formation of syncytium (seen by inverted light microscope) in Sf9 cells after 7 hours low pH shift, but no fusion activity before the pH shift.

FIGURE 46.9. Schematic diagram summarizing the overall mechanisms of viral RNA synthesis and the role of VP1, VP4, and VP6 proteins in RNA synthesis.

The Largest Protein VP1 Is the RNA-Dependent RNA Polymerase

The first indication that the largest BTV protein, VP1 (149.5 kD) is the virus polymerase protein came from sequence comparison with other DNA and RNA polymerases and from an *in vitro* polymerase assay that used a crude extract of insect cells infected with a recombinant baculovirus expressing only BTV VP1.^{37,131} Subsequent *in vitro* studies have used purified recombinant protein and have shown that VP1 exhibits a processive replicase activity in the absence of any other viral proteins and initiates BTV minus-strand synthesis *de novo*.¹³ Recombinant VP1 copies each of the plus-strand RNA segments fully, from the smallest (822 nt) to the largest BTV plus-strand RNA of 3,954 nt, either individually or simultaneously in a single *in vitro* reaction, to produce a dsRNA duplex that is RNase I resistant, and RNase III sensitive. Synthesis of dsRNAs from capped single stranded RNA (ssRNA) templates is significantly higher than from uncapped ssRNA templates and could be further enhanced by priming with complementary terminal dinucleotide. Some evidence for template specificity was suggested by the fact dsRNAs were not synthesized from nonviral ssRNA templates unless they were fused to specific BTV sequences. These data contrast those of rotavirus and reovirus; in rotavirus the assigned polymerase protein (VP1) is only active in the context of the inner shell protein VP2,¹²⁸ and recombinant reovirus polymerase $\lambda 3$ is generally incapable of synthesizing *de novo* reovirus RNA, although short RNA transcripts were observed.^{113,123}

Three distinct domains of VP1, PD, NTD, and CTD have been synthesized in bacteria and purified in soluble form. The purified PD fragment, but not the NTD or CTD fragments, was able to bind NTP, but none had catalytic activity when tested individually.¹⁴⁰ When all three were mixed together *in vitro*, however, RdRp activity was reconstituted and was shown to depend on the signature catalytic Glycine Aspartic Aspartic (GDD) motif (aa 763–765) within the PD domain. Plausibly, the PD possesses catalytic activity but requires the other two domains to stabilize the overall structure. It is noteworthy that in reovirus $\lambda 3$, the large N- and C-terminal domains form a cage around the centrally placed polymerase domain, holding it rigid and preventing movement during the catalytic cycle.¹²³

The Minor Protein VP4 Is the mRNA Capping Enzyme

Although VP1 has been shown to be active as the viral RdRp, it does not form the methylated cap structure found at the 5' end of BTV mRNAs. Formation of the cap structure requires at least three key enzymatic activities: (1) an RNA triphosphatase (RTase) that hydrolyzes the 5'-triphosphate terminus of the mRNA to a diphosphate; (2) a (GTase) that caps the diphosphate terminus with GMP via a 5'-5' triphosphate linkage, and (3) a guanine-N7-methyltransferase (N7MTase) that adds a methyl group to the N7 position of the blocking guanosine. An additional nucleoside-2'-O-methyltransferase (2'OMTase) is also required for BTV and reovirus transcripts, to methylate

the 2'-hydroxyl group of the ribose of the first nucleotide (namely type 1 cap).

Recombinant, purified VP4 (76.4 kD) synthesizes type 1-like “cap” structures *in vitro* that are identical to those found on authentic BTV mRNA. VP4 is unique as it possesses methyltransferases, guanylyltransferase, and RNA triphosphatase activities in the absence of any other viral protein.^{80,97,98} This is notably different from other viral capping enzymes, for example, those of vaccinia virus, where completion of capping is dependent on a complex of three proteins.¹³⁷ The atomic structure of the protein has revealed how a single protein orchestrates all of these activities.¹¹⁹

VP6 Helicase

Genome replication of the *Reoviridae* is fully conservative and logically requires helicase activity, either to unwind the dsRNA ahead of the transcriptase protein or to separate the parental and newly synthesized RNAs following transcription. For BTV, VP6 has a strong binding affinity for both ssRNAs and dsRNAs, possesses nucleoside triphosphatase activity, and in isolation has the ability to unwind dsRNA substrates *in vitro*.¹¹⁴ Similar to other helicases, VP6 is hexameric and forms ring-like structures in the presence of BTV RNAs.⁶⁵ Using reverse genetics it has been shown that VP6 is an integral part of the transcription complex that is necessary for primary replication and requires the *cis*-acting sequences for replication or packaging.⁸³ How substrates pass from one component of the transcription complex to the next remains a significant question however.

Core transcripts are not produced at equimolar amounts from the 10 segments of BTV⁵⁶; the smaller genome segments are generally the most frequently transcribed, although segment 6 RNA (encoding NS1) is synthesized more abundantly than the smallest segment, segment 10 RNA (encoding NS3).

In vivo, the replication of BTV, like other members of the family, uses a packaged plus-strand RNA as template for the synthesis of a “minus” strand, and then a dsRNA, which remains within nascent progeny particles. The basis of copy choice between the plus- and minus-strand RNAs and the full roles of each protein in the process remain to be defined.

Protein Synthesis and Virus Replication

BTV-specific proteins are detectable within 2 to 4 hours postinfection, and the rate of protein synthesis increases rapidly until 11 to 13 hours postinfection.⁵⁵ In addition to the seven structural proteins of the virion, four virus-encoded nonstructural proteins, NS1, NS2, NS3, and NS3A, are synthesized in BTV-infected cells. Infection of mammalian cells with BTV, in contrast to insect cells, leads to a rapid inhibition of cellular macromolecular synthesis and the induction of a robust apoptotic response triggered by multiple apoptotic pathways.^{90,116}

The large nonstructural proteins NS1 (64 kD) and NS2 (41 kD) are highly conserved (96%) among BTV serotypes (see review 101,108), and they are synthesized abundantly early in infection, suggesting that they are essential for virus replication. The synthesis of NS1 and NS2 in BTV-infected cells coincides with that of two virus-specific intracellular structures, tubules and the viral inclusion bodies (VIBs), respectively, which are characteristics of orbivirus-infected cells.²² In contrast to the amounts of NS1 and NS2 produced, the steady-state levels of the small viral nonstructural proteins, NS3 and NS3A (26

and 25 kD, respectively) are highly variable (from being barely detectable to being highly expressed) and are dependent on the host cell species.

NS1 and Tubules

The 64-kD protein NS1 of BTV constitutes up to 25% of the virus-specified proteins in virus-infected cells and assembles into tubular structures within the cytoplasm.^{53,132} Tubules are characteristic of all orbivirus infection (e-Fig. 46.3) and are formed by helically coiled ribbons of NS1 dimers.⁵⁰

NS1 appears to regulate BTV protein synthesis through binding specifically to BTV mRNAs at the conserved extreme 3' hexanucleotide sequence (5' ACUUAC 3').^{12a} NS1 is essential for virus replication, as NS1 knockout and point mutants introduced by reverse genetics are lethal. NS1 thus appears to be a regulator of viral gene expression, which distinguishes between cellular RNAs with a 3' poly A tail and viral mRNAs by binding directly to the 3' end of viral mRNAs. However, the relationship of this activity to tubule formation, if any, remains to be established.

Virus Assembly Site, Inclusion Bodies, and Role of NS2

Shortly after release from the endosome, core particles become very rapidly associated within “virus inclusion bodies” (VIBs). VIBs initially appear as granular material scattered throughout the cell, but then coalesce to form a prominent perinuclear inclusion.^{14,21,57,63} The major component of VIBs is the NS2, and expression of NS2 alone results in the formation of inclusion bodies that are indistinguishable from the VIBs.^{89,127} Co-expression of core structural proteins has shown that although VP1, VP3, VP4, and VP6 all co-localize with NS2 inclusions in the absence of viral replication, the core surface protein VP7 requires the co-expression of VP3 to be recruited (Fig. 46.10A,B). Electron microscopy using recombinant NS2 and virion proteins in different combination has suggested NS2 associates with assembling particles.^{63,89}

NS2 is phosphorylated in BTV-infected cells by casein kinase II (CKII).⁸⁹ Phosphorylation sites of NS2 have been mapped to two serine residues at positions 249 and 259, and furthermore it was shown that the unmodified NS2 failed to assemble into VIBs, although smaller oligomeric forms readily assembled.⁸⁹ NS2 phosphorylation was not necessary for either its RNA-binding properties or its ability to interact with the viral core proteins, but it may control the level of VIBs formation to provide the matrix for viral assembly.

Consistent with this, when a cell line constitutively expressing NS2 was infected with BTV followed by first treatment with actinomycin D and subsequent addition of bromouridine, the newly synthesized labeled BTV transcripts were identified within the VIBs.⁶³ Purified recombinant NS2 has strong ssRNA binding activity *in vitro*, and BTV RNAs are preferentially bound over nonspecific RNAs^{73,79,126} via *cis*-acting sequences distributed throughout the coding and noncoding regions of the different genome segments.⁷³ Chemical and enzymatic structure probing of the preferentially bound regions has suggested NS2 recognition of unique hairpin-loop secondary structures.⁷³ The RNA binding activity of NS2 could explain how BTV mRNAs are selected from the pool of cellular messages for incorporation into assembling virus particles, but it remains unclear how only a single copy of each genome segment is included in newly formed

FIGURE 46.10. Interaction of NS2 and viral proteins.

A: Confocal microscopy showing the co-localization of three polymerase complex proteins and NS2 in BTV-infected cells.

B: Same with two major core proteins, VP3 and VP7 with NS2. Note that VP7 co-localizes with NS2 only in the presence of VP3.

C: Schematic showing the interaction of NS2/VIB with BTV proteins and the bluetongue virus (BTV) single-stranded RNA (ssRNA). "P" represents phosphorylation of NS2, which is responsible for formation of viral inclusion bodies (VIBs).

core particles. Plausibly NS2 could bring the viral RNAs into proximity via the formation of decameric complexes.^{15,29} Phosphorylation of NS2 may modulate these activities, VIB formation, and the interaction with other viral proteins or transcripts⁸⁹ (Fig. 46.10C), and following core assembly dephosphorylation could allow disassembly of VIBs and the release of immature virus particles into the cytoplasm.

Requirement for Primary Replication Versus Secondary Replication by Reverse Genetics System

The assembly of a distinct early replicase complex in BTV-infected cells was discovered by using a reverse genetics system. It was shown that repeated transfection of BTV *in vitro* generated transcripts improved the recovery of infectious BTV by approximately 50-fold when compared to single transfection.¹² Stimulation did not require the complete set of transcripts; those encoding VP1, VP3, VP4, VP6, NS1, and NS2 representing the presumptive transcriptase complex (VP1, VP4 and VP6), the major subcore protein (VP3), and the two NS proteins associated with VIBs and BTV protein synthesis sufficed (Fig. 46.11). The same study also suggested that helicase VP6 acted early in replication and that “capped” transcripts were not essential for packaging, as the second transfection could use capped or uncapped transcripts with the same level of rescue. Interestingly, the addition of a transcript encoding VP7 to the primary transfection mix, which would allow completion of the core particle, did not stimulate virus recovery, suggesting that a fully competent replicase complex requires only a VP3-based substructure. These data may indicate that an *in vitro* model of BTV core assembly is possible.

Capsid Assembly

BTV structural proteins have an inherent capacity to self-assemble into core-like particles (CLPs) and virus-like particles (VLPs) that lack the viral genome^{35,36} (e-Fig. 46.4), and their assembly by expression of viral structural proteins in insect cells (see review by 103) has shed much light on the assembly pathway.

FIGURE 46.11. The recovery of bluetongue virus (BTV) with T7 transcripts. Number of plaques per μg RNA recovered when BHK cells were pretransfected with either 7 transcripts (S1, S3, S4, S6–S9), 6 transcripts (lacking S7), 5 transcripts (lacking S6 and S7), or no (0) transcripts, followed by transfection with all 10 capped transcripts.

VP3 Assembly and Subcore Formation

A key question in VP3 assembly is whether the decamer observed in the core structure⁴² is an identifiable intermediate in the assembly process. Deletion of the dimerization domain of VP3 abolished subcore formation, but decamer formation was not affected.⁶⁴ This suggests that decamers are the first stable assembly intermediate and that decamer-decimer interactions via the dimerization domain drive the assembly of the complete VP3 subcore.

Based on CLP assembly, both VP1 and VP4 have been shown to independently associate with the VP3 layer,^{71,91} and a VP1+VP4 complex also interacts directly with the VP3 decamer in solution.⁶⁴ By contrast, BTV RNAs interact with VP3 *in vitro* very efficiently but fail to associate with VP3 decamers under the same conditions. BTV cores may thus initiate with the complex formed by VP1 and VP4 with VP3 decamers and subsequently recruit the polymerase complexes prior to completion of the assembly of the VP3 subcore (Fig. 46.12). Unlike VP1 and VP4, it has not been possible to confirm the location of VP6 in the core, although it is likely to be at the fivefold axes together with VP1 and VP4. The newly synthesized mRNAs are also probably packaged during the assembly of subcores, and it is likely that RNA replication takes place after subcore or core formation. Recently, using a cell-free *in vitro* translation system, evidence has been obtained of the assembly of BTV RNA-protein complexes *de novo*. Following translation of the core replicase components, the addition of 10 ssRNAs representing noncapped positive-strand copies of each genomic segment leads to assembly into a complete BTV core. Such *in vitro* assembled cores were functional, as the 10 packaged ssRNA molecules were converted to 10 dsRNA genomic segments. Furthermore, reconstituted cores isolated from sucrose velocity gradients were infectious in *Culicoides* insect vector cell culture, generating all the viral proteins and subsequently leading to the recovery of infectious particles.⁷² Using this *in vitro* virus assembly system it should be possible to delineate the role and order of each component in the assembly pathway as well as the requirements for genome packaging, an exciting future prospect.

VP7 Assembly and Core Formation

The mismatch between the number of subunits in the VP3 and VP7 layers of the core poses an interesting problem for an icosahedral structure. Core assembly has been shown to depend on trimer formation, the precise “shape” of the trimers being sufficient to drive the formation of the tight lattice of 260 trimers on the core surface.^{69,70} Sheets of VP7 probably form around different nucleation sites instead of a cascade of trimer associations originating from a single nucleation site, as suggested by structural studies.⁴² A likely pathway of core assembly is therefore that a number of strong VP7 trimer-VP3 contacts act as multiple equivalent initiation sites and that a second set of weaker interactions then “fill in the gaps” to complete the outer layer of the core. The “T” trimers (of the P, Q, R, S, and T trimers) at the threefold axes of symmetry act as nucleation, whereas “P” trimers that are farthest from the threefold axis and closer to the fivefold axis are the last to attach.⁷⁰

Assembly of the Outer Capsid

Following the assembly of the core particle, the viral outer capsid proteins, VP2 and VP5, are added. Cryo-EM experiments have aided our understanding of how the outer capsid

FIGURE 46.12. Schematic diagrams showing the growing VP3 decamers and assembly of polymerase complex with the VP3 decamer prior to the formation of VP3 protein shell and showing the possible pathway of VP7 trimer assembly: **Left**, the positions of VP7 protomeric unit and position of VP3 layer, and **right**, the sequential assembly of various VP7 trimers on VP3 scaffolds.

proteins interact with the outer VP7 layer of the core,^{91,144} but our understanding of where in the cell these proteins are added to the core is still limited. The addition of VP2 and VP5 abolishes transcription activity so the addition of the outer capsid is likely to be a highly regulated process to prevent premature shut-off of transcription. Baculovirus expression of cores with VP5 and VP2 leads

to assembly of a VLP mimicking the authentic virions.³⁵ The VP7 trimers of the core serve as the platform for the deposition of the VP2 and VP5¹⁴⁴ (e-Fig. 46.5). Each triskelion VP2 trimer interacts with four VP7 trimers at its underside and via the hub that connects to the VP7 “Q” trimer by a wall of density. Most VP7 molecules, the exception being the VP7 at the icosahedral

threefold axis (T type), are covered by the connections, and the top of the T trimer is clearly exposed to the exterior.

The globular-shaped VP5 trimers fill the gaps created by the three legs of the VP2 triskelion and sit right above the type II and III channels of the core (e-Fig. 46.6). The VP5 trimer makes relatively few weak interactions with its adjacent VP7 trimers, possibly to permit conformational changes of VP5 during the penetration process.

Overall, the principal protein–protein contacts of two outer capsid proteins of the BTV appear to be with the outer layer of the core rather than with each other, and this may be related to the distinct steps mediated by each protein during virus entry into uninfected cells.

Trafficking, Maturation, and Egress of Progeny Virions

Although the core particles are assembled in VIBs, the assembly of VP2 and VP5 onto the core to form mature infectious virus particles does not occur within these structures.^{39,40} Biochemical evidence has confirmed that the outer capsid proteins VP2 and VP5, an internal core protein VP6 and the nonstructural glycosylated NS3 protein, all interacts with membrane raft domains.

Interaction of Raft with BTV Proteins

Raft domains occur in both internal vesicular membranes, and the plasma membrane of cells and their disruption with methyl beta cyclodextrin alters the distribution of VP5 and NS3 and decreases the relative BTV viral titer.⁸ VP5 possesses a highly conserved sequence (WHXL) that is present in the Soluble N-ethylmaleimide sensitive attachment protein receptors (SNAREs) regulatory protein Synaptotagmin I (Syt1), and disruption of this sequence by alanine scan perturbed the association of VP5 with lipid rafts.⁸ The SNARE domains of cellular proteins interact with the negatively charged lipid phosphatidylinositol (4,5) bisphosphate [PI(4,5)P₂], present in membrane rafts,⁵¹ and depletion of cellular PI(4,5)P₂ by expression of phos-

phatase 5ptaseIV or its relocation to endosomal-like structures by Arf6/Q67L expression inhibited normal BTV maturation despite not altering BTV protein expression levels.¹⁰ EM showed the attachment of viral particles to the outer surface of vesicle-like structures in the cytoplasm that were absent in PI(4,5)P₂-depleted cells. NS3 is normally localized to the Golgi complex, and it is likely that reduction in cellular PI(4,5)P₂ perturbs the generation of vesicles from the distal Golgi stack. NS3 also interacts with both outer capsid proteins and core surface protein VP7,¹⁰ suggesting that NS3 might bring the newly assembled BTV core and the outer capsid components together for formation of mature virion particles. PI(4,5)P₂ plays an important role in the generation and trafficking of intracytoplasmic vesicles via the cytoskeleton, and in BTV-infected cells virus particles are found associated with the vimentin intermediate filaments,²² the disruption of which prevents normal virus release.^{7,9} The data are consistent with a role of internal vesicular membranes in providing a scaffold for virus assembly and the use of those vesicles for trafficking assembled virus to the plasma membrane.

NS3 and Cellular Exocytic Pathways in BTV Release

The canonical view of the release of nonenveloped viruses from infected cells is that of cell lysis. However, there is an increasing appreciation that complex trafficking and budding strategies are also involved. In the case of BTV, both mechanisms appear to act with a preponderance of lysis during mammalian cell infection, but essentially none during infection of vector insect cells.^{16,17,58}

The only membrane proteins that are encoded by BTV are NS3 (229 aa) and its shorter form NS3A (216 aa), which lacks the N-terminal 13 amino acids^{34,68} (Fig. 46.13). Both proteins have been found associated with smooth-surfaced, intracellular vesicles.⁵⁹ NS3/NS3A proteins comprise a long N-terminal and a shorter C-terminal cytoplasmic domain, which are connected by two transmembrane domains and a short extracellular domain.^{2,6,143} Co-expression of NS3 and NS3A with baculovirus-expressed VLPs (acting as surrogates

FIGURE 46.13. BTV NS3 protein. **A:** A schematic diagram showing the organization of NS3 protein domains. BTV NS3 is an integral membrane protein with two transmembrane domains (TMs) and contains the two late domain motifs PPXY and PS/TAP that recruit the components of cellular ESCRT complexes and N-terminal residues that recruit cellular calpactin p11. **B:** Confocal microscopy showing the co-localization of NS3 and two outer capsid proteins.

for authentic virions) stimulated VLP release, and NS3 protein has been observed at the site of VLPs release.⁵⁹ The NS3 protein of BTV and AHSV is cytotoxic when expressed in mammalian or insect cells,^{34,136} and it has been suggested that it may function as a viroporin, facilitating virus release by inducing membrane permeabilization.⁴⁴

Using the yeast two-hybrid analysis, the cytoplasmic N-terminal region of NS3 specifically interacts with S100A10,⁶ a Ca^{2+} insensitive member of the S100 family that forms a heterotetrameric complex with two heavy chains of annexin II (also known as annexin A2) to form the calpactin complex in cells. Calpactin

is involved in trafficking of proteins and membrane targeting (reviewed in 100). The cytoplasmic domain of NS3, situated at the C-terminus specifically with the BTV outer capsid protein VP2 suggesting that NS3 facilitates virus engagement with host cell membrane trafficking machinery (Fig. 46.13).

Using reverse genetics, which allows the introduction of mutations into the virus genome it was possible to investigate the roles of NS3 and NS3A in the virus replication.¹⁷ A virus synthesizing only NS3 but not NS3A was able to propagate in and release from mammalian cells efficiently (Fig. 46.14A–C). However, growth of a mutant virus expressing only NS3A was

FIGURE 46.14. NS3 mutant viruses affect virus trafficking and egress. Electron micrograph of Baby Hamster Kidney cells (BHK) cell section infected with wild-type (A), or mutant BTV expressing only NS3 not NS3A (B), or only NS3A not NS3 (C). Parallel infections in vector insect cells with wild-type (D), NS3 (E), or NS3A (F) mutant viruses. Election micrographs of infected Baby Hamster Kidney cells (BHK) cells sections with wild-type (G), mutations in Tsg101 (H) and VP2 (I) binding domains of NS3. Note the changes in virus trafficking and egress in each mutant virus versus wild-type virus infection. (Reprinted from Celma CC, Roy P. A viral nonstructural protein regulates bluetongue virus trafficking and release. *J Virol.* 2009;83(13):6806–6816, with permission.)

severely attenuated, although protein expression, dsRNA synthesis, and particle assembly in the cytoplasm were observed. Two of three single amino acid substitutions in the N-terminal 13 residues of NS3 that interact with S100A10/p11 showed phenotypically similar effects. In insect cells virus replication was apparent, albeit with reduced titer, but whereas wild-type particles were found predominantly in cytoplasmic vesicles in insect cells, mutant viruses were scattered throughout the cytoplasm and not confined to vesicles (Fig. 46.14D–F). Therefore, the extreme amino terminus of NS3 is required for trafficking in mammalian cells via interaction with S100A10/p11, whereas both NS3 and NS3A were required for efficient BTV growth in insect cells.

NS3 also possesses a late (L) domain motif (PSAP) similar to those found in budding enveloped viruses (see Fig. 46.13).^{16,142} L domains engage with the vacuolar protein sorting pathway, a cellular budding network that gives rise to multivesicular bodies (MVBs).³³ BTV NS3 interacts with human tumor-susceptibility gene 101 protein (Tsg101), and both NS3 and NS3A of BTV and AHSV bind *in vitro* with similar affinity to human Tsg101 and also to its ortholog from *Drosophila melanogaster*. This interaction is mediated by the conserved PSAP motif in NS3. Mutations at PSAP motif by RG systems left nascent BTV particles tethered to the cellular membrane (Fig. 46.14G,H).¹⁶ Similar effects were seen with a mutant virus in which VP2 interacting C terminal sequences of NS3 were altered (Fig. 46.14I). BTV morphogenesis apparently makes use of multiple egress pathways, one of which is the NS3-Tsg101 interaction, whereas the second is NS3-mediated virus trafficking via S100A10/p11. Presumably these were acquired by the virus during replication in mammalian cells with the virus using NS3 as a multifunctional adaptor protein to bridge the gap between newly formed virus particle and the cell components that enable virus egress.^{6,16}

EFFECTS ON HOST CELLS

BTV infection causes hemorrhagic disease in ruminants and induces cell death through apoptosis. In BTV-infected mammalian cells, both the biochemical and morphological hallmarks of apoptosis are observed within 24 hours of infection, including activation of nuclear factor kappa B (NF- κ B), caspase-3, DNA fragmentation, membrane blebbing, and cellular shrinkage (e-Fig. 46.7). Those changes are not observed in insect (*Culicoides*) cells, although these cells are efficient for BTV replication.⁹⁰ In cell culture, both extrinsic (caspase-8 activation) and intrinsic (caspase-9 activation) pathways play roles in BTV apoptosis. BTV-induced cell death appears to be predominantly due to apoptosis rather than necrosis, and a correlation may exist between CPE, apoptosis of host cells, and pathogenesis.¹¹⁶ Microscopic analysis of primary cultures of endothelial cells from sheep and bovine lungs infected with BTV suggests that apoptosis may contribute to the pathogenesis of bluetongue disease in the mammal.¹⁹ BTV infection induces an early and transient NF- κ B response through the degradation of I κ B α , and virus titers are higher in the presence of an NF- κ B inhibitor (SN50), indicating that NF- κ B has a role in initiating the antiviral environment. BTV infection also induces the translocation of interferon regulatory factors (IRF-3 and IRF-7) into the nucleus, although as with the NF- κ B response, they are not sustained.

The morphology of cellular microfilaments changes extensively during infection (see review 20) in keeping with observations that BTV proteins, virus particles, VIB, and tubules are intimately associated with the intermediate filaments of cytoskeleton.^{7,22,63}

CLINICIAN SIGNS AND PATHOGENESIS

Orbiviruses produce a spectrum of disease, from subclinical infection to high morbidity and mortality, depending on virus strain and host species.⁷⁷ Following introduction by insect bite, virus migrates to local lymph nodes and then subsequently spreads to spleen, thymus, and other lymph nodes (Fig. 46.15). Orbivirus infections can induce prolonged cell-associated viremias in vertebrate hosts. Prolonged bluetongue viremias are particularly notable in cattle, which can serve as asymptomatic virus reservoirs. After experimental inoculation of calves, infectious virus can be detected in blood for up to 8 weeks and viral nucleic acid for up to 20 weeks.⁷⁷ BTV binds to glycoporphins on the surface of bovine and ovine erythrocytes,²⁰ where it can remain in an infectious state for prolonged periods, possibly for the lifetime of the red blood cell.⁷⁷

The role of leukocytes in cell-associated viremias is less certain. BTV has been recovered from bovine mononuclear cells during the early stage of infection.⁷⁷ Active replication of virus in these cells, however, appears to be restricted to proliferating cells. *In vitro* studies of bovine lymphocytes have shown multiple subpopulations to be susceptible to infection. Helper T-cell subsets replicate BTV to high titer and undergo cytopathic infection, whereas cytotoxic suppressor and null cells become persistently infected without lysis. Monocyte-macrophages appear to be targets for infection with AHSV.

BTV and related orbiviruses (e.g., AHSV and Epizootic Hemorrhagic Disease Virus (EHDV)) result in disease with pathophysiologic features resembling other viral hemorrhagic fevers.^{67,78,129} Infection of endothelial cells is followed by infection of vascular smooth muscle cells and

FIGURE 46.15. Transmission cycle of bluetongue virus (BTV) between the ruminant host and *Culicoides* vector.

pericytes, which then undergo lytic infections, resulting in virus-induced vascular injury and a cascade of pathophysiologic events characterized by capillary leakage, hemorrhage, and disseminated intravascular coagulation. Clinically these events are manifested by edemas, hemorrhages of blood vessels, conjunctiva and skin, hypotension, and shock. Other clinical features include fever, lameness, excessive salivation, and congestion. However, the swollen cyanotic tongue that gives bluetongue its name is rare. Mortality rate is variable and dependent on breed and species. There are some correlations between endothelial infection and severity of disease; sheep show the most severe clinical signs and generally have extensive endothelial infections, but cattle, where infections are often subclinical, generally have only minimal endothelial.⁷⁷

Both BTV and EHDV can cross the placenta, and infection of pregnant cattle and sheep can result in fetal infection, abortion, or congenital anomalies.⁷⁷ Live-attenuated BTV vaccines and BTV contamination of vaccines for other animals have been shown to be a principal cause of teratogenesis.⁹³

Similar to the differences in pathology seen when BTV and EHDV infect sheep and cattle, AHSV affects members of the Equidae family differently; horses are the most severe disease, whereas donkeys and mules generally show mild clinical signs. Zebras, a natural reservoir for AHSV, exhibit viremia but do not manifest clinical signs of infection. Severity of AHS disease in horses ranges from a pulmonary form with close to 100% mortality to African horse sickness fever, which is characterized by high temperature for 1 to 3 days but 100% recovery. The pulmonary form is most common in outbreaks among naïve populations of animals.

EPIDEMIOLOGY

Evidence for antigenically different types of BTV with strain variation in virulence was first reported in 1948.⁹² For a long time the epidemiology of BTV was focused on animals with clinical signs. However the introduction of simple serologic tests in the 1970s led to the recognition of the high prevalence of subclinical infections of BTV and other orbiviruses in ruminants throughout the tropics and subtropics. As with many arbovirus transmitted diseases, outbreaks are highly dependent on the density of vector and vertebrate hosts and whether the vertebrate host is immunologically naïve. In endemic zones, infections are generally subclinical, but in naïve populations large epizootic outbreaks with severe disease are observed. More recently, sequencing studies reveal accumulation of point mutations that suggest that BTV strains currently circulating in Asia and Africa may have become separated a long time ago.⁹⁵

Although BTV has been detected worldwide, in the past Europe has experienced only infrequent and short-lived incursions of the disease. However, since 1998, several different BTV serotypes have emerged in Europe, some of which can now be considered endemic. The repeated introduction and establishment of these viruses, together with their persistence over several years, has resulted in the deaths of several million animals and provides evidence for an epidemiologic *step-change*.⁸⁴ The later outbreak of BTV serotype 8 in Northern Europe, which started in 2006, was the result of a separate introduction of the virus. The route of introduction is unclear, but the outbreak

strain shows most sequence similarity to one found in Sub-Saharan Africa.⁷⁵

Earlier serologic surveys have shown that many BTV serotypes (including those that have recently caused outbreaks in the Mediterranean region) have been present on the periphery of Europe for several decades, most notably in sub-Saharan Africa, Cyprus, Turkey, and the Middle East.⁹⁶ The reason for the concentrated emergence around 1998 is therefore unclear. Sequence data indicate separate origins and routes of introduction for each of the BTV strains that emerged in Europe; therefore, a single change in the virus or trade patterns can be ruled out. One possibility that has been raised is that climate change may have contributed to changes in the period of activity and size of vector populations.³⁸ Certainly the assumption that *Culicoides obsoletus* and *C. pulicaris*, which are more common in North and Central Europe than the African vector *Culicoides imicola*, were unable to transmit virus sufficiently to sustain a large outbreak has proved wrong.

AHSV is confined mainly to the African continent, although as with BTV prior to 1998, AHSV has caused sporadic, short-lived outbreaks of disease in Europe and the Middle East. A previous outbreak of AHS (1987–1991), caused by an infected zebra, was limited to the south west of the Iberian Peninsula.

In conclusion, molecular epidemiology has provided us with tools for the analyses of geographic variants in orbiviruses and their relationship to ecosystems and arthropod vectors. From recent studies based on a European BTV scenario, it could be concluded that (a) weather patterns play an important role in transmission and (b) BTV can be transmitted by a wider range of vector species than previously realized.

IMMUNE RESPONSE

Neutralizing antibodies are produced within 8 to 14 days of natural BTV infections.³² Very good correlation is found between the induction of neutralizing antibodies against the major outer capsid protein VP2 and protection of sheep against homologous challenge.^{54,109} Infection of sheep and cattle with two serotypes confers protection against other serotypes that had not been included in the inoculums.¹¹⁸ Similarly, antibodies raised with a mixture of recombinant VP2 proteins of various serotypes not only neutralized the infectivity of the homologous strains but also cross-neutralized certain heterologous viruses.¹³⁰ It is possible that cross-reactive epitopes exist on VP2, but other mechanisms may also be involved in this cross protection.

In addition to antibody response, cell-mediated immunity (CMI) also plays a role in recovery from infection and protection against reinfection. Cytotoxic (CD8+) cells responsive *in vitro* to BTV antigen were demonstrated in the blood of cattle and sheep during the first week of infection and peaked at 2 weeks after infection.²³ Immunity was restricted by the major histocompatibility complex (MHC) and thus was host specific. Further evidence for CMI in sheep has been obtained by demonstrating cytotoxic T-lymphocyte (CTL) responses and protection of recipient twins by passive transfer of immune lymphocytes depleted of B cells.¹¹⁸ These data were also supported by *in vitro* studies, and BTV antigen-specific ovine T-cell lines have been shown to become stimulated by a number of

different BTV serotypes.¹²¹ Despite this, the specificity and location of antigenic sites for T cells are still poorly understood. Studies of BTV in mice identified cross-reactive CTL, but other studies have suggested that serotype-specific CTL responses may occur as well.¹¹⁸ Ovine T-cell lines established from sheep immune to BTV-1 showed serotype specificity and were directed against antigenic sites on the VP2 outer capsid protein,¹²⁰ but other T-cell lines reacted with antigens localized on VP5 and inner core proteins. Indeed, when expressed individually, each of the structural and nonstructural BTV proteins has been shown to induce a CTL response.⁶² Antibody-dependent, cell-mediated cytotoxicity may also play a role in protective immunity.⁶²

VACCINES

Live-attenuated BTV vaccines have been developed by serial passage in embryonated chicken eggs; because of the number of multiple serotypes, multivalent vaccination has generally been used in endemic areas.¹ Similarly, live-attenuated virus vaccines for nine serotypes of AHSV have been developed.²⁵ These are administered as doses of two polyvalent vaccines consisting of a total of seven serotypes of the nine serotypes and are considered to induce cross-protective immunity to remaining one or two serotypes. Optimal immunity and protection from disease, however, is best provided by serotype-specific vaccines.²⁵ This was demonstrated in an AHSV outbreak in Spain, where polyvalent vaccines failed to give protective immunity against AHSV-4, the serotype responsible for the disease.²⁵ Despite their success in endemic areas, the use of attenuated vaccines has some drawbacks. Teratologic effects as a result of vaccination with attenuated BTV are well documented.^{61,93,111} Furthermore, viremia following vaccination in both laboratory experiments and in the field has been sufficient for the vaccine strain to be transmitted.^{28,111} Due to the segmented nature of the virus genome, reassortment of genes between strains that co-infect the same animal is possible.¹¹⁷ This has also been observed in the field: A BTV-16 strain circulating in Italy in 2002 was found to be a reassortment between BTV-2 and BTV-16 live-attenuated vaccine strains.⁵ Therefore, although attenuated vaccines for BTV may offer a route to control disease, they are not suitable for a program designed to eradicate the disease in an area.

Due to the proven effectiveness of naturally attenuated vaccines, reverse genetics technology has now been exploited to rationally design vaccines for BTV and AHSV. To this end, BTV mutants with deletions in essential genes have been recovered by growth in complementing cell lines. The growth properties of these mutant viruses were consistent with the necessary characteristics for a disabled infectious single cycle (DISC) vaccine.⁸³ Vaccination with the DISC virus strains abolished viremia, and detectable clinical disease in sheep following the virulent virus challenge.⁸² The advantage of a DISC vaccine over traditionally attenuated viruses is that the mutations limiting virulence are defined and the challenge virus results in no detectable viremia in infected animals; therefore, the possibility of reassortment is reduced and it is possible to distinguish between vaccinated and convalescent animals. Although still experimental, DISC vaccines could offer a promising alternative to currently available BTV vaccines.

Recently, chemically inactivated BTV vaccines were used for mass vaccination of sheep and cattle in many countries in

Northern Europe. These inactivated virus vaccines have been demonstrated to be safe and immunogenic in animals but are currently only available for a limited number of serotypes.¹¹⁰ Inactivated vaccines, provided quality control is rigorously implemented, are a significant advance on the attenuated vaccines. However, vaccine production involves the growth of large amounts of infectious virus prior to inactivation.

The recent European BTV outbreaks and the need to distinguish vaccinated and convalescent animals have also led to development of pox virus-based vaccines for BTV. These vaccines are based on the expression of the virus VP2 protein, and the canarypox vector has been efficient at eliciting protective response in sheep.¹¹

Extensive clinical trials have been carried out in recent years with baculovirus-generated recombinant BTV proteins, assembled as CLP and VLP.¹⁰⁴ Initial studies using unpurified VP2 and VP5 proteins of BTV-10 have demonstrated that VP2 alone at high doses ($>100 \mu\text{g}/\text{dose}$) could give protection in sheep against virulent virus challenges, whereas much less VP2 was needed for complete protection when mixed with a low amount of VP5 ($\sim 20 \mu\text{g}/\text{dose}$), suggesting that the two proteins acting synergistically are probably sufficient for vaccine development. Complete protection against AHSV infection was achieved when horses were vaccinated with as little as $5 \mu\text{g}$ of baculovirus expressed recombinant AHSV-4 VP2.¹⁰⁵

Recombinant VLPs, consisting of VP2, VP3, VP5, and VP7, were assessed in vaccination trials with the rationale that VLPs are biologically and immunologically similar to virions and elicit high titers of neutralizing activity against the homologous and, to some extent, heterologous BTV serotypes. The protective activities of VLP vaccination have been assessed in a number of vaccination trials using susceptible Merino sheep. The data demonstrated that long-lasting protection against homologous BTV challenge could be achieved by vaccination with VLP (using as little as $10 \mu\text{g}$ of VLP, of which VP2 is only $1\text{--}2 \mu\text{g}$). Some cross-protection was also achieved, depending on the challenge virus and the amounts of antigen used for vaccination.¹⁰⁶ More recently, a number of VLPs for European serotypes have been prepared and strong protection against virulent virus challenge in a variety of European sheep breeds.¹¹⁵ In contrast, sheep trials with CLPs which consists of only VP3 and VP7 indicated that only partial protection (with only slight fever) against virus challenge could be achieved. Animals showed strong group-specific antibody responses but, as expected, no neutralizing antibodies. Because CLP are conserved across the various serotypes, they could have potential as a candidate universal vaccine, which could at least mitigate bluetongue disease and inhibit virus spread.

PERSPECTIVE

Significant progress has been made in recent years in understanding the structure and biochemistry of the BTV replication cycle. The function of BTV proteins as enzymes in the transcription complex, as structural proteins in capsid assembly, and as mediators of host-virus interaction—especially in virus entry, egress, and pathogenicity—have all been described. BTV is thus very well characterized, genetically and structurally, and it is reasonable to suppose that other Orbiviruses will have similar core functions. A recent development of some significance

for the future has been the development of a reverse genetics system for the virus, which will allow these molecular functions to be confirmed and refined in the context of a replicating virus. It should also allow the development of precisely engineered attenuated vaccines capable of inducing a vigorous immune response thereby preventing infection while excluding the possibility of reversion or reassortments that limit current live vaccines. Therefore, the application of the findings of basic virology should result in vaccine improvement, disease prevention, and management. Significant challenges, however, remain. Most of what has been learned of BTV and related Orbiviruses has focused on the replication in mammalian cells, principally cells in culture. The replication and spread of BTV in whole animals is less studied, and the replication and spread in *Culicoides* species even less so. These should improve with the development of a tractable small animal model for the former and the whole genome sequence of *Culicoides* for the latter. The identification of host cell factors critical to BTV replication may be important here as they could inform the construction of a suitable transgenic model and indicate why certain species of *Culicoides* are preferred for transmission. Assuming developments in these areas, the whole biology of BTV infection, including pathogenesis, breed susceptibility, and transmission should become as well understood as the molecular aspects described. When they do, the mechanisms of virus evolution and emergence, and the roles played by each host in the process should become apparent. As for the application of basic virology, it is likely that these developments too will result in better control of orbivirus disease in the future.

Retroviral Vectors, Packaging Lines, and Gene Therapy Perspectives

The retrovirus family, the *Retroviridae*, are a large and diverse group of viruses found in all vertebrates. These viruses replicate through an extraordinary and unique life cycle, differentiating them sharply from other viruses. The virion particles generally contain a genomic RNA, but upon entry into the host cell, this RNA is reverse transcribed into a DNA form of the genome that is integrated into the host chromosomal DNA. The integrated form of the viral DNA, the provirus, then serves as the template for the formation of viral RNAs and proteins that assemble progeny virions. These features of life cycle—especially the reverse flow of genetic information from RNA to DNA, and the establishment of the DNA in an integrated form in the host genome—are the defining hallmarks of the retroviruses. This life cycle also accounts for many of their diverse biological activities. The creation of the proviral DNA confers on the viruses a powerful ability to maintain a persistent infection in the face of a host immune response and to enter the germ line, permitting the vertical transmission of virus.

The retroviruses have played a unique role in the history of molecular biology. They have attracted attention on several grounds.

- **Biochemistry:** The viral replication enzymes, including the reverse transcriptase (RT) and integrase (IN), are extraordinarily useful tools in manipulating nucleic acids *in vitro* and *in vivo*. Through the preparation of complementary DNAs (cDNAs), RT has been crucial for studies of messenger RNA (mRNA) synthesis and gene regulation.
- **Pathogenicity:** Retroviruses are known as major pathogens affecting nearly all vertebrates. HIV-1, the agent of the AIDS pandemic, will probably cause more human death and suffering than all but a handful of pathogens in recorded history.
- **Markers of evolutionary history:** The insertion of a provirus into the germ line provides a Mendelian tag that marks an event at a particular time in evolution. The inheritance of that tag can then be used to follow speciation, population migrations, and evolution of species.
- **Insertional activation of oncogenes:** The integration of retroviral DNA is inherently mutagenic; retrovirus replication thus

causes gross alterations of host genes and patterns of gene expression. When insertions lead to tumor formation, the locations serve to identify new oncogenes.

- **Transduction:** Retroviruses can acquire host sequences in the formation of acutely transforming genomes. The identity, structure, and expression of these genes has provided much of our current knowledge of the routes by which normal growth control can be subverted by genetic alterations.
- **Gene delivery vectors:** The structure of transforming viruses provided a model for the use of retroviruses to deliver therapeutic genes efficiently and cleanly into cells. Retroviruses now serve as major tools in the medical black bag of gene therapists.

This chapter will describe the replication and molecular biology of the retroviruses, concentrating on the most broadly conserved aspects of the life cycle. Because of the magnitude of the retroviral literature, citations here cannot be comprehensive, and referencing has been selective and concentrated on more recent publications. The distinctive features of the human retroviruses, especially the lentiviruses and spumaviruses, will be addressed in much more detail in other chapters. A comprehensive review of retroviral biology (called the *Retroviruses*; [108]) is still current, and should be consulted for additional details of almost all aspects of their replication.

TAXONOMIC CLASSIFICATION

The retroviruses were originally classified by the morphology of the virion core as visualized in the electron microscope. Examples of the appearance of the virions in these micrographs are presented in Figure 47.1. The virion particles are spherical, and are surrounded by an envelope consisting of a lipid membrane bilayer. The surface is studded by projections of an envelope glycoprotein. There is a spherical layer of protein under the membrane, and an internal nucleocapsid (or nucleoid) whose shape varies characteristically from virus to virus. The shape and position of the nucleocapsid core was historically used as the major classifying feature of the retroviral genera. A-type viruses were defined as those forming intracellular structures with a characteristic morphology, a thick shell with a hollow, electron-lucent center. These particles are now appreciated as representing an immature capsid on route toward the formation of other structures. This term is thus no longer in use to denote a virus classification, though it is used to describe the structures formed by some virus-related intracellular retrotransposons (the intracisternal A-type particles, or IAPs).^{307,349} B-type viruses show a round but eccentrically positioned inner core. C-type viruses assemble at the plasma membrane, and contain a central, symmetrically placed, spherical inner core. The D-type viruses assemble in the cytoplasm, via an A-type intermediate, and upon budding exhibit a distinctive cylindrical core.

These older classifications have been useful in partially defining the various genera of the family *Retroviridae*, but the number of genera have now been expanded on the basis of new criteria. The genera have recently been formalized and given new names by the International Committee on Taxonomy of Viruses. The alpharetroviruses, betaretroviruses, and gammaretroviruses are considered “simple” retroviruses, while the deltaretroviruses, epsilonretroviruses, lentiviruses, and spumaviruses are

TABLE 47.1 Retrovirus Genera

Name	Examples	Morphology
Alpharetrovirus	Avian leukosis virus (ALV) Rous sarcoma virus	C type
Betaretrovirus	Mouse mammary tumor virus (MMTV) Mason-Pfizer monkey virus (M-PMV) Jaagsiekte sheep retrovirus	B, D type
Gammaretrovirus	Murine leukemia viruses (MuLV) Feline leukemia virus (FeLV) Gibbon ape leukemia virus (GaLV) Reticuloendotheliosis virus (RevT)	C type
Deltaretrovirus	Human T-lymphotropic virus type 1, 2 Bovine leukemia virus (BLV) Simian T-lymphotropic virus type 1, 2, 3	Rod-shaped core
Epsilonretrovirus	Walleye dermal sarcoma virus Walleye epidermal hyperplasia virus 1	—
Lentivirus	Human immunodeficiency virus type 1 Human immunodeficiency virus type 2 Simian immunodeficiency virus (SIV) Equine infectious anemia virus (EIAV) Feline immunodeficiency virus (FIV) Caprine arthritis encephalitis virus (CAEV) Visna/maedi virus	Rod/Cone-shaped cores
Spumavirus	Human foamy virus	Immature

considered “complex.” The simple viruses encode only the Gag, Pro, Pol, and Env gene products; the complex viruses encode these same gene products but also an array of small regulatory proteins with a range of functions. The properties of the viruses belonging to each of these genera are summarized briefly in the following section. Representative members of each genus are listed in Table 47.1.

Alpharetroviruses

The alpharetroviruses are simple retroviruses characterized by a C-type morphology, and are typified by the avian sarcoma and leukosis viruses (ALSV). The genome contains *gag*, *pro*, *pol*, and *env* genes, with no additional known genes; *pro* is at the 3′ end of *gag* and in the same reading frame. The transfer RNA (tRNA) primer is tRNA^{trp}. The viruses are widespread

in many avian host species. The ALSV members are classified into 10 subgroups (termed A–J) by their distinct receptor utilization. The first four subgroups represent exogenous viruses of chickens; the subgroup E includes a family of endogenous chicken viruses; and subgroups F and G include endogenous viruses of pheasants.

Betaretroviruses

The betaretroviruses are simple retroviruses characterized by either a “B-type” morphology, with a round eccentric core, or “D-type” morphology, with a cylindrical core. The best-known examples are the mouse mammary tumor virus (MMTV) and the Mason-Pfizer monkey virus (MPMV). Assembly occurs in the cytoplasm via an “A-type” intermediate, and the completed immature particle is then transported to the plasma membrane

FIGURE 47.1. Electron micrographs of representative virion particles. The diameters of all the particles are approximately 100 nm. **A:** Type A particles. Intracisternal A particles in the endoplasmic reticulum. **B:** Betaretrovirus. Mouse mammary tumor virus, MMTV; type B morphology (*top*, intracytoplasmic particles; *middle*, budding particles; *bottom*, mature extracellular particles). **C:** Gammaretrovirus. Murine leukemia virus, MLV; type C morphology (*top*, budding; *bottom*, mature extracellular particles). **D:** Alpharetrovirus. Avian leukosis virus; type C morphology (*top*, budding; *bottom*, mature extracellular particles). **E:** Betaretrovirus. Mason-Pfizer monkey virus, MPMV; type D morphology (*top*, intracytoplasmic A-type particles; *middle*, budding; *bottom*, mature extracellular particles). **F:** Deltaretrovirus. Bovine leukemia virus, BLV (*top*, budding; *bottom*, mature extracellular particles). **G:** Lentivirus. Bovine immunodeficiency virus (*top*, budding; *bottom*, mature extracellular particles). **H:** Spumavirus. Bovine syncytial virus (*top*, intracytoplasmic particles; *middle*, budding; *bottom*, mature extracellular particles). **I:** Betaretrovirus. Mouse mammary tumor virus, MMTV; type B morphology, visualized by negative staining with phosphotungstic acid. **J:** Gammaretrovirus, visualized as pseudoreplica stained with uranyl acetate. **K:** Lentivirus. Purified cone-shaped cores of equine infectious anemia virus (*top*, cores visualized by shadow casting technique; *bottom*, cores visualized by negative staining with phosphotungstic acid). **L:** Budding retroviral particles visualized by scanning electron microscopy. (Micrographs courtesy of Dr. Matthew Gonda, and reproduced from Coffin JM, Hughes SH, Varmus HE, eds. *Retroviruses*. Cold Spring Harbor, NY: Cold Spring Harbor Press; 1997).

and budded. The genomes contain *gag*, *pro*, *pol*, and *env* genes, and the *gag*, *pro*, and *pol* genes are all in different reading frames. The genome of MMTV contains an additional gene termed the *sag* gene for superantigen. The viruses also contain a dUTPase region as part of the *pro* open reading frame (ORF).¹⁵⁶ The tRNA primer is tRNA^{Lys}-3 or tRNA^{Lys}-1,2. There are both exogenous and endogenous viruses in this genus. Examples are found in mice, primates, and sheep.

Gammaretroviruses

The gammaretroviruses are simple viruses characterized by a C-type morphology. This genus has the largest number of members known, including the murine leukemia viruses (MuLVs), the feline leukemia viruses (FeLVs), and the gibbon ape leukemia virus (GALV). The genome contains only *gag*, *pro*, *pol*, and *env* genes; the *gag*, *pro*, and *pol* sequences are in the same reading frame, and the Gag-Pro-Pol protein is expressed by translational readthrough of a stop codon at the end of *gag*. The genome primer is most often tRNA^{Pro} or tRNA^{Glu}. The murine viruses are divided into subgroups by their distinct receptor utilization. Many exogenous and endogenous viruses are found in diverse mammals; examples have been isolated from reptiles and birds. A novel gammaretrovirus termed XMRV (for xenotropic murine leukemia virus-like virus) was identified in human prostate cancer tumors,⁶⁰⁴ but recent work strongly suggests that the virus was a recombinant derived during tumor passage in nude mice.⁴⁵²

Deltaretroviruses

The deltaretroviruses are complex viruses characterized by a C-type morphology. The most famous examples are the human T-lymphotropic viruses (HTLVs) and the bovine leukemia virus (BLV). The genome contains *gag*, *pro*, *pol*, and *env* genes; the *gag*, *pro*, and *pol* genes are present in three different reading frames, and expression of the Gag-Pro-Pol protein requires two successive frameshifts. In addition, the genomes contain regulatory genes termed *rex* and *tax* that are expressed from an alternatively spliced mRNA. These gene products control the synthesis and processing of the viral RNAs. The tRNA primer is tRNA^{Pro}. No closely related endogenous viruses are known, and the exogenous viruses are only rarely found in a few mammals.

Epsilonretroviruses

The epsilonretroviruses are complex viruses characterized by a C-type morphology. The prototype is the walleye dermal sarcoma virus (WDSV). The genomes contain *gag*, *pro*, *pol*, and *env* genes; the *gag*, *pro*, and *pol* genes are in the same reading frame. They also contain one to three additional genes termed *ORFs A*, *B*, and *C*. The *ORF A* gene is a viral homolog of the host cyclin *D* gene, and so may regulate the cell cycle. The viruses use tRNA^{His} or Arg as primers. The only known examples are exogenous viruses in fish and reptiles.

Lentiviruses

The lentiviruses are complex viruses characterized by a unique virion morphology, with cylindrical or conical cores. The most important example is the human immunodeficiency virus type 1 (HIV-1), but nonprimate viruses in the genus include the caprine arthritis encephalitis virus (CAEV) and visna virus. The genomes express *gag*, *pro*, *pol*, and *env* genes; *gag* is in one reading frame, and *pro-pol* in another. A single frameshift is

used to express Gag-Pro-Pol. The Pol region of the nonprimate lentiviruses includes a domain for dUTPase. A number of accessory genes are also expressed. In HIV-1, these genes are *vif*, *vpr*, *vpu*, *tat*, *rev*, and *nef*; these genes control transcription, RNA processing, virion assembly, and host gene expression, and inactivate host restriction systems. The tRNA primer is tRNA^{Lys}1,2. A large number of exogenous viruses in this genus have been found in diverse mammals, but the only endogenous sequences are relatively distant from these viruses.

Spumaviruses

The spumaviruses are complex viruses with a unique virion morphology, containing prominent spikes on the surface and a central but uncondensed core. The prototype example is the human foamy virus. The virion is assembled in the cytoplasm and budded into the ER and plasma membrane. There is probably only a single cleavage of the Gag protein near the C-terminus, and no major change in morphology during maturation. The genomes express *gag*, *pro*, *pol*, and *env* genes, and also at least two accessory genes known as *tas/bel-1*, and *bet*.^{177,380} The *tas* gene encodes a transcriptional transactivator. Unique features are the separate expression of the Pol protein from a spliced mRNA and the presence of large amounts of reverse transcribed DNA in the virion.³⁹⁰ The genome contains a second transcriptional start site near the 3' end of the *env* gene. The tRNA primer is tRNA^{Lys}1,2. A number of exogenous viruses have been found in diverse mammals, and distantly related sequences are present as endogenous elements in the human genome.

Evolutionary Relationships

The sequences of the various retroviral genomes have been compared and used to determine the relatedness of any pair.³⁷⁵ A number of phylogenetic trees can be constructed using *gag*, *pro*, *pol*, or *env* genes, and in most aspects these trees are similar. A tree based on comparisons of the *pol* gene (Fig. 47.2) shows the clustering of viruses within each of the main genera. However, it is important to realize that a phylogenetic tree is not necessarily identical to an evolutionary history, and that the history that led to the formation of the known genera is not necessarily simple. It is noteworthy that there is no obvious clustering of all the simple viruses into a group apart from all the complex viruses. Thus, complex viruses probably arose from the simple ones more than once, with many evolving through the independent acquisition of separate genes.

The retroviruses are related to viruses of other families. The retroviral RTs show close sequence similarity to the polymerases of the hepadnaviruses and the caulimoviruses, which also replicate by reverse transcription. The retroviruses also show extensive similarity in both *gag* and *pol* gene sequences to the retrotransposons, endogenous mobile elements with long terminal repeats (LTRs), and to retroposons, elements without LTRs. Retroviral RTs show more distant similarity to proteins encoded by the group II mitochondrial introns and by the retrons, elements in myxobacteria and rare isolates of *E. coli*; to telomerase, an RT responsible for maintenance of the chromosomal termini in eukaryotes; and slight similarity to the DNA polymerases of viruses and hosts.³⁷⁴

Transforming Viruses

During the replication of any retrovirus, replication-defective variants can arise through deletion or recombination events.

FIGURE 47.2. Phylogenetic reconstruction of representative exogenous retroviruses using reverse transcriptase sequences. The BEASTv1.6.1 tree¹⁴⁴ was created using two independent Bayesian MCMC chains (length of 1 million, 20% burn) run under relaxed clock (uncorrelated exp; 143) and rate heterogeneity among sites (gamma distribution with 8 categories). Monophyletic taxon sets consisting of alpha, beta, delta, epsilon, gamma, lenti, and spuma were also used in the model. The posterior probabilities label each node and branch lengths are scaled to expected substitutions per site. (Prepared by Marcella McClure, Montana State University, Bozeman, MT.)

Such mutants or variants can be propagated as a mixed virus culture along with the wild-type parent. In these mixtures of two genomes, the replication-competent parent acts as a helper virus to provide the missing replication functions *trans* for the replication-defective virus. If a newly acquired gene product is mitogenic or antiapoptotic for the host cell, or in more subtle ways alters the growth of the cell, the recombinant may become a potent oncogenic virus. A large number of such transducing viruses have been isolated and characterized as derivatives of one or another of the replication-competent parent viruses. A partial listing of the most intensely studied of these viruses is presented in Table 47.2.

VIRION STRUCTURE

Retrovirus virions are initially assembled and released from infected cells as immature particles containing unprocessed Gag and Gag-Pol precursors of the proteins that eventually

make up the mature virus. The immature virion morphology is spherical, with a characteristic electron-lucent center. The virions have been described as a “protein vesicle,” to suggest some fluidity in the interactions between the individual Gag proteins that make up the particle. Upon maturation, the precursor proteins are cleaved, and the structure and morphology of the virion change drastically. The mature retrovirus particle is a spherical structure, roughly 100 nm in diameter. The size of the virions in a given preparation is not highly homogeneous but rather varies over a fairly wide range, suggesting that a discrete, highly ordered structure may not exist. After processing of the Gag precursor during virion maturation, the CA protein collapses to form a more ordered paracrystalline core, but even then the overall diameter of the virion is heterogeneous and suggestive of considerable disorder. The virions exhibit a buoyant density in sucrose in the range of 1.16 to 1.18 g/ml. The sedimentation rate of the particles is typically about 600 S. The virions are sensitive to heat, detergent, and formaldehyde.

TABLE 47.2 Examples of Acute Transforming Retroviruses

Parental virus	Transforming virus	Transduced gene(s)

ALV, avian leukosis virus; MSV, murine sarcoma virus; MuLV, murine leukemia virus.

Virion Proteins

The stoichiometry of the various viral gene products in the virion is not very firmly established, but estimates suggest that about 1500 Gag precursors are present per particle. After processing, all cleavage products are thought to be retained, suggesting equimolar presence of these proteins in the mature virions. The levels of the Pol proteins are typically about one-tenth to one-twentieth those of the Gag proteins, corresponding to about 100 to 200 molecules per virion. The levels of the Env proteins are highly variable among the viruses. For the gammaretroviruses, the levels of Env are close to that of Gag;

perhaps 1200 monomers, or 400 trimers, are present per virion. For the lentiviruses, the levels of Env per virion are much lower, possibly as low as 10 trimers per virion.⁶⁷¹

Nomenclature

The cleavage of Gag, Pol and Env precursors forms the products in the mature infectious virions. These proteins are named by convention by a two-letter code: MA for matrix or membrane-associated protein; CA for capsid; NC for nucleocapsid; PR for protease; DU for dUTPase; RT for reverse transcriptase; IN for integrase; SU for surface protein; and TM for transmembrane protein.³²³ The localization of these proteins in the mature virion is not known with great precision, but a highly schematic version of the generic retrovirion can be drawn (Fig. 47.3).

Arrangement of Virion Components

The genomic RNA is highly condensed in the virion by its association with the nucleocapsid protein, NC. The complex is contained within a protein core largely composed of the capsid protein CA, another Gag gene product. The shape of the core is different among the various retroviral genera, and is a distinguishing feature of the genera. In most of the viruses the core is roughly spherical, but in some cases can be either conical or cylindrical. In all the viruses the core is surrounded by a roughly spherical shell consisting of MA, which in turn is surrounded by the lipid bilayer of the virion envelope. The virion membrane contains the envelope glycoprotein, with the TM subunit present as a single-pass transmembrane protein anchor, and the SU subunit as an entirely extravirion protein bound to TM. The envelope proteins for those viruses examined closely have been found to reside in the membrane as trimers.

ORGANIZATION OF THE RNA GENOME

The viral genome is a dimer of linear, positive-sense, single-stranded RNA (ssRNA), with each monomer 7 to 13 kb in size. The viral genomic RNA is present as a homodimer of two identical sequences, and thus the virions are functionally diploid. The dimer is maintained by interactions between the two 5' ends of the RNAs in a self-complementary region termed the **dimer linkage structure (DLS)**. The RNA genome is generated by normal host transcriptional machinery, and thus exhibits many of the features of a normal mRNA. The RNA is capped at the 5' end, using the common m7G5'ppp5'G_{mp}

FIGURE 47.3. Generalized retrovirion structure and components. A highly schematic view of the arrangement of viral gene products within the virion particle. The two-letter nomenclature for each protein is indicated.

FIGURE 47.4. The organization of the retroviral RNA genome. The single-stranded RNA genome is depicted as a curved line. From 5' to 3' along the RNA, the features include a 5' cap structure; R, a sequence block repeated at both 5' and 3' ends; U5, a unique 5' sequence block; pbs, the primer binding site and site of initiation of minus strand DNA synthesis; Ψ , the major recognition site for the packaging of the viral RNA into the virion particle; the *gag*, *pol*, and *env* genes; ppt, the polypurine tract and site of initiation of the plus strand DNA synthesis; U3, a unique 3' sequence block; the second copy of the R sequence; and finally, a 3' poly(A) sequence.

structure; and contains a string of poly(A) sequence, about 200 long, at the 3' end.

A number of sequence blocks are so important that they have been named to facilitate descriptions of their functions in the life cycle (Fig. 47.4). These key sequences are clustered at the termini of the RNA. A short sequence, the R (for repeated) region, is so called because it is present twice in the RNA: once immediately after the cap at the 5' end and again at the 3' end, just before the poly(A) tail. Downstream of the 5' R lies another sequence, termed U5 for unique 5' sequence, which includes one of the att sites required for proviral integration. The U5 region is followed by the primer binding site, an 18-nt sequence at which a host tRNA is hybridized to the genome and the site of initiation of minus-strand DNA (msDNA) synthesis.

The region downstream from the primer binding site (pbs) often contains the major signals for the encapsidation of viral RNA into the virion particle, in sequences called the **Psi element**. The region also often contains a **major splice donor site for the formation of subgenomic mRNAs**. The bulk of the RNA sequences that follow are coding regions for the viral proteins. The genomes of all the replication-competent retroviruses contain at a minimum three large genes, or open reading frames: from 5' to 3' along the genome, the genes are termed *gag*, for group-specific antigen; *pol*, for polymerase; and *env*, for envelope. The three genes in the simple retroviruses occupy nearly all the available space in the center of the genome.

Downstream of the genes lies a short polypurine tract (ppt), a run of at least nine A and G residues. The ppt is the site of initiation of plus strand DNA (psDNA) synthesis. The ppt is followed by a sequence block termed U3 for unique 3' sequence; this region contains a number of key cis-acting elements for viral gene expression, and one of the att sites required for DNA integration. The U3 abuts the 3' copy of the R region, which is followed by the poly(A) tail. As will be demonstrated, the R, U5, U3, pbs, and ppt sequences all play important roles in reverse transcription.

OVERVIEW OF THE LIFE CYCLE

The retroviruses replicate through a complex life cycle. A short summary of the steps of the cycle is as follows (a schematic view is shown in Fig. 47.5):

- Receptor binding and membrane fusion
- Internalization and uncoating
- Reverse transcription of the RNA genome to form double-stranded linear DNA
- Nuclear entry of the DNA
- Integration of the linear DNA to form the provirus
- Transcription of the provirus to form viral RNAs
- Splicing and nuclear export of the RNAs
- Translation of the RNAs to form precursor proteins
- Assembly of the virion and packaging of the viral RNA genome
- Budding and release of the virions
- Proteolytic processing of the precursors and maturation of the virions

Changes in the Viral Genome

A quick perusal of this list reveals that the life cycle begins with an RNA genome, passes through an intracellular DNA intermediate, and is completed with a return to an RNA form in the progeny virus particle. An overview of the structures of the genome at various times in this cycle is presented in Figure 47.6. The RNA genome of the virion contains short terminal repeats (the R region) at its termini. During reverse transcription, to be seen below, sequence blocks termed U5 and U3 are duplicated, so that the resulting dsDNA is longer at both ends than the RNA template. This DNA thus contains long terminal repeats (the LTRs, consisting of sequence blocks U3, R, and U5) at both ends. The next step is the integration of the DNA to form the provirus; the integrated provirus is collinear with the preintegrative DNA, and retains the LTRs (except for one or two base pairs lost at the termini during the course of integration). Finally, the DNA is forward transcribed by the RNA polymerase II system to produce the progeny RNA genome. Transcription is initiated at the U3-R boundary of the 5' LTR, and the transcripts are processed and polyadenylated at the R-U5 boundary of the 3' LTR, recreating the exact structure of the input RNA, complete with its short terminal repeats. This RNA is packaged and exported in virion particles. Each step is described in more detail in the next section.

THE VIRUS RECEPTORS

To enter a cell and initiate infection, all retroviruses require an interaction between a cell surface molecule—a receptor—and

Retroviral Replication Cycle

FIGURE 47.5. A schematic view of the retrovirus life cycle. The major steps in the replication of a typical retrovirus are indicated, including those in the early phase of the life cycle, extending from the infecting virion (*top left*) to the formation of the integrated provirus, and those in the late phase of the life cycle, extending from the provirus to the formation of mature progeny virus (*right*).

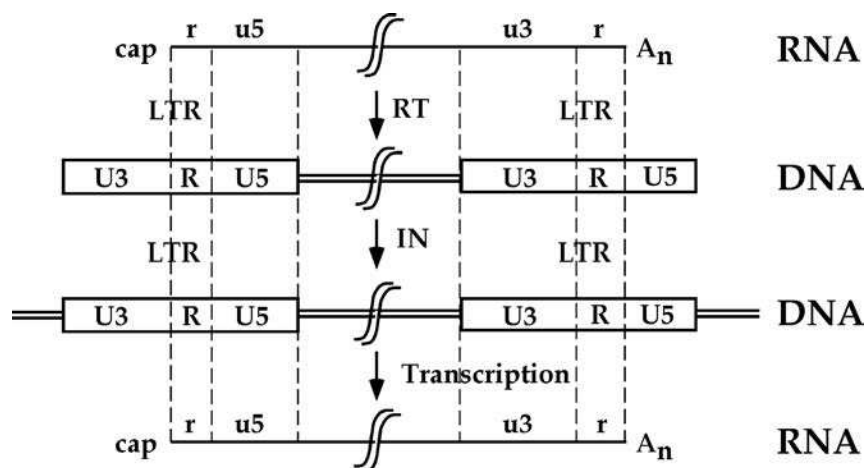

FIGURE 47.6. Structures of the termini of the viral RNA and DNA genomes at various stages of the viral life cycle. Sequence blocks in RNA are indicated by lower case, and those in DNA by upper case. The structure of the RNA genome in the virion particle is indicated at the top. Reverse transcription of the RNA soon after infection involves the duplication and translocation of u5 and u3 sequence blocks, and results in the formation of a double-stranded DNA molecule containing two terminal LTRs. The integration of the DNA genome occurs at the terminal sequences, establishing a provirus that is collinear with the preintegrative DNA. The forward transcription of the provirus is initiated at the U3/R border in the provirus; the resulting RNAs are cleaved and polyadenylated at the r/u5 border, recreating a viral RNA genome (*bottom*) identical to the infecting RNA.

TABLE 47.3 Retrovirus Receptors

Virus(es)	Receptor name(s)	Function	References
MuLV, ecotropic	CAT-1	Basic amino acid transporter	(154,282,386,428,607)

the envelope protein on the virion surface. The interactions are complex, involving an initial binding, drastic conformational changes in the envelope protein, an induced fusion of the viral and cellular membranes, and the internalization of the virion core into the cytoplasm. The SU subunit of Env is thought to make the major initial contacts with receptor, and the TM subunit is thought to be most important for membrane fusion. The reorganization of the two lipid bilayers—one on the virion and one on the cell—to join them and evert the core into the cell is a remarkable process. The details of these complex processes are not understood for any retrovirus, and the whole Env protein is likely to be involved in efficient entry. However, there is a great deal of information about the identity and structures of the receptors used by various retroviruses. It is apparent that these viruses utilize an extraordinarily diverse set of cell surface molecules as receptors (Table 47.3; see 41,581,624 for reviews).

An important tool in the analysis of receptor utilization is the phenomenon of **virus interference**, or **superinfection resistance**. Cells chronically infected by a particular virus cannot be infected by any virus that must enter by the same receptor as used by the first virus though they are readily infected by viruses that utilize a distinct receptor. The reason is that the expression of Env protein by the first virus binds to the receptor intracellularly, preventing its export to the cell surface or its function as a receptor for newly applied virus. The phenomenon allows for the rapid classification of those viruses that use a common receptor.

The properties of the receptors of the major retroviral genera are summarized in the following section.

Alpharetrovirus Receptors

The receptor for the A subgroup of avian viruses was identified as encoding a membrane-anchored glycoprotein with sequence

similarity to the ligand-binding repeat of the low-density lipoprotein receptor (LDLR).^{33,653} Its identity as the true receptor has been confirmed by correlating its genetic map position with the *tv-a* locus.³² The *tv-b* locus, encoding the receptor for both the B and D subgroups of the ASLV, encodes a protein termed CAR1, unrelated to *tv-a* but with sequence similarity to the receptors for tumor necrosis factor (TNF) and the Fas death receptors.⁷³ The intracellular portion of the molecule contains the sequence of a “death domain,” present on other cytotoxic receptors, and can trigger the apoptotic death of the cell upon ligand binding. The *tv-c* locus is closely linked to *tv-a* but encodes an unrelated surface protein, one with strong sequence similarity to mammalian butyrophilins, members of the immunoglobulin family.¹⁵⁷ The *tv-e* locus is present in turkey but not chicken, and allows for infection by the subgroup E viruses. The gene was cloned by its sequence similarity to the chicken *tv-b* locus.⁴

Betaretrovirus Receptors

The receptor for MMTV was cloned by co-segregation of DNA markers with virus susceptibility in mouse/hamster radiation chimeric cell lines, and so identified as the transferrin receptor *tfr1* on mouse chromosome 16.⁵²⁰ A second receptor for the betaretroviruses was also identified. The type D simian viruses, including MPMV and SRV-1, -2, -4, and -5, show cross-interference with three type-C viruses: feline endogenous virus (RD114), baboon endogenous virus (BaEV), and avian reticuloendotheliosis virus (REV), suggesting that they all utilize a common cell-surface receptor. Gene transfer of a human cDNA library into nonpermissive mouse cells was used to identify a gene that conferred susceptibility to infection by RD114.⁵⁸³ The cDNA encoded a protein nearly identical to the previously cloned human Na⁺-dependent neutral-amino-acid transporter named B⁰.^{288,498} Consistent with this similarity, expression of

the RD114 receptor in NIH 3T3 cells resulted in enhanced cellular uptake of L-³H]alanine and L-³H]glutamine.

Gammaretrovirus Receptors

Several receptors for various gammaretroviruses are known.⁵⁸¹ The first example, the mouse receptor used by the ecotropic MuLVs, was identified by gene transfer to nonpermissive human cells, selecting for susceptibility to MuLV infection.⁸ The gene encodes a membrane glycoprotein of 67 kDa containing a total of 14 membrane spanning domains. The normal function of the protein has been identified as a transporter or permease for cationic, basic amino acids.²⁹² The receptor, termed mCAT-1, was shown to be identical to γ^+ , the previously characterized transporter in mammalian cells. The gene for mCAT-1 is now known as *Atrc1*.

The amphotropic receptor is utilized by a group of MuLVs derived from wild mice able to infect a wide range of mammalian species, including humans. The receptor was cloned by selection for susceptibility to virus infection after transfection of cDNA libraries into nonpermissive CHO cells,^{154,386} and by its homology to the gene for the previously identified GALV receptor.⁶⁰⁷ The gene, known variously as *Ram1* or *GLVR2* or *rPiT-2*, encodes a 652-amino acid protein that functions as a sodium-dependent phosphate symporter.²⁸² The synthesis and stability of the receptor is regulated by phosphate levels, and its downregulation by virus infection results in substantial reduction in phosphate uptake by cells.

The receptor utilized in common by GALV, simian sarcoma-associated helper virus (SSAV), and FeLV-B is widely expressed in many mammals, including primates, cat, dog, mink, rabbit, and rat (but not mouse), as well as in some avian species. The human receptor is termed GLVR1 or hPiT-1.^{265,426} The sequence of the gene predicts the existence of 10 membrane-spanning segments, and a large third intracellular loop. The protein is a sodium-dependent phosphate symporter.^{282,428} Specific amino acid changes introduced into the fourth extracellular loop can block FeLV-B and SSAV infection without affecting GALV, suggesting that these various viruses interact in slightly different ways with the receptor. A remarkable feature of infection by FeLV-B via feline PiT-1 is a requirement for the co-expression of an endogenous Env-like protein dubbed FeLIX.¹³

The xenotropic MuLVs are viruses present as proviruses in the mouse germ line but unable to infect inbred mouse cells. The polytropic MuLVs are also endogenous viruses with a wide host range that includes many mammalian species. Xenotropic and polytropic MuLVs cross-interfere to various extents in nonmouse species and in wild Asian mice, suggesting that they might use a common receptor for infection. The mouse receptor for the polytropic viruses was cloned by gene transfer, and was identified with the *Rmc1* gene.⁶⁵⁰ The human xenotropic receptor mediates infection by both the xenotropic and polytropic viruses, as well by the XMRV isolate.⁶⁴⁷ The gene encodes a membrane protein related to the yeast Syg1p protein (suppressor of yeast G alpha deletion). Its function is unknown, but its multiple membrane-spanning segments and its sequence suggests that it may act as a G-coupled receptor.

The receptor utilized by the subgroup C feline leukemia viruses (FeLV-C) encodes a protein with 12 membrane-spanning domains with significant sequence similarity to the D-glucarate transporters of bacteria and nematodes.⁴⁹⁴ The binding of virus

to this receptor may be responsible for its pathogenesis, a block in erythroid differentiation.

Additional receptors for other gammaretroviruses are known to exist. Three newly characterized porcine endogenous retroviruses (PERV-A, -B, and C) have been tested in interference assays with each other and with murine viruses using the known receptors; all three apparently utilize distinct and novel receptors.⁵⁸⁵ The PERV-A receptor has been identified and is likely a G protein-coupled receptor.¹⁶⁰

Deltaretrovirus Receptors

The receptor for the bovine leukemia virus (BLV) is highly similar to the delta subunit of the AP-3 complex.^{26,576} AP-3 is involved in intracellular trafficking of clathrin-coated vesicles and is not thought to be present on the cell surface. The properties of the receptor are not yet well established.

Lentivirus Receptors

The first receptor identified for any retrovirus was the CD4 molecule, established as essential for infection by HIV-1.^{122,294,357} CD4 is an important surface protein on T cells, and with few exceptions serves to define the helper subset of T cells. CD4 is also expressed at significant levels on dendritic cells, macrophages, and on certain cells in the brain, likely astrocytes rather than cells of neural origin. The limited distribution of expression of CD4 accounts well for the tropism of HIV-1, largely restricted to helper T cells and macrophages. There may be other routes of entry utilized at lower efficiency: antibody to virus, for example, can promote virus entry into cells by the Fc receptor. Receptor-negative dendritic cells can take up virions via binding to the DC-SIGN molecule and deliver them efficiently to T cells to promote their infection, but even here infection of the recipient cells requires their expression of the CD4 receptor.^{199,309}

Early work established that although CD4 was sufficient to mediate virus binding to a cell surface, it was not sufficient to mediate virus infection and entry. For example, rodent cells and other cells of nonprimate origin could not be successfully infected by HIV-1 even if they were engineered to express human CD4. Searches for genes that would render such cells sensitive to virus infection ultimately led to the identification of various members of the chemokine receptor family, notably CCR5 and CXCR4, as coreceptors needed to mediate the postbinding steps of membrane fusion and virus entry.^{152,171,552} Antibodies to the coreceptor as well as the natural ligand for these molecules, the chemokines themselves, can block virus entry. Variants of SIV and HIV-1 have been identified that are CD4-independent, needing only a chemokine receptor for infection; the existence of these viruses suggests that the chemokine receptors might have been the primary receptor for a primordial virus. Further proof of the importance of the chemokine receptor is the existence of a mutant allele of the gene encoding CCR5 in the human population, a 32-bp deletion, that confers dramatic virus resistance to homozygous individuals. More discussion of the roles of CD4 and the co-receptors in virus entry will be presented in Chapter 49 on HIV-1.

PENETRATION AND UNCOATING

Once virus particles have bound to the receptor, the virion and host membranes fuse together, and the virion core is delivered

into the cytoplasm of the infected cell. Entry may require, or be promoted by, membrane regions of special lipid composition termed lipid “rafts”.^{334,364,484} Virus particles may “surf” or slide across the outside of the cell to preferred locations where fusion or entry inside the cell can occur.³²² For most retroviruses, the processes of fusion and entry are thought to be pH independent; that is, they are not dependent on an endosomal acidification step to induce a pH-dependent change in the conformation of the envelope. Thus, for these viruses fusion can occur at the cell surface. However, the ecotropic and amphotropic MuLVs and the subgroup A avian viruses are inhibited by drugs that block acidification; these viruses thus likely enter by passage through endosomes.

The process of fusion involves major rearrangements of the Env proteins, and especially includes the exchange of disulfide bonds that exist within or between the TM and SU subunits of Env. The process for the MuLVs seems to be controlled by Ca²⁺ levels, and involves TM–SU intersubunit disulphide-bond isomerization and SU dissociation.⁶¹⁷ Entry by HIV-1 probably also involves the removal or shedding of SU.

The processes of uncoating or opening of the core to permit reverse transcription to begin are poorly understood. It is clear that the previous processing of the Gag precursor to the mature Gag proteins is required; immature virions are uninfectious and cannot initiate reverse transcription, and mutants that prevent particular cleavages of the Gag protein are similarly blocked. A large number of mutant viruses with other alterations in the *gag* gene have been shown to be defective in early steps of infection, before reverse transcription, but the functions of Gag proteins at this stage remain uncertain. Mutant virions that are fragile and uncoat prematurely or, conversely, are resistant to disassembly, are poorly infectious, suggesting that the timing of uncoating may be critical.¹⁷⁸ There are indications that host factors are important in these early stages. In the case of HIV-1, the host protein cyclophilin A, which interacts with CA, is required for the efficient initiation of reverse transcription.⁵⁵⁹ A plausible role for this protein is to facilitate virion disassembly.²²⁹ The TRIM proteins restrict virus infection at this time (see Early block to infection by Trim5a section).

Small molecule inhibitors have been used to demonstrate a role of the cytoskeleton in virus entry, and furthermore to suggest that viruses may utilize different entry pathways in different cell lines.²⁹³ Biochemical analyses of these early events are made difficult by the presence of large numbers of defective particles that are probably not on the infectious pathway and that tend to obscure the properties of the rare particles that are on this pathway. Nevertheless, examination by fluorescence microscopy of GFP-tagged virion particles during infection has indicated that intracellular movement likely occurs along cytoskeletal fibers.³⁷⁷

REVERSE TRANSCRIPTION

The reverse transcription of the viral RNA genome into a dsDNA form is the defining hallmark of the retroviruses, and the step from which these viruses derive their name. The course of reverse transcription is complex and highly ordered, involving the initiation of DNA synthesis at precise positions and translocations of DNA intermediates that result in duplication of sequence blocks in the final product (for reviews see 201,590).

The major steps in the reaction are relatively well established, largely through the analysis of reactions carried out *in vitro* in purified virion particles (the so-called “endogenous reaction”).

Reverse transcription normally begins soon after entry of the virion core into the cytoplasm of the infected cell. The reaction takes place in a large complex, roughly resembling the virion core, and containing Gag proteins including NC, RT, IN, and the viral RNA.⁶⁶ The signal that triggers the onset of DNA synthesis is not known, though it may be as simple as the exposure of the viral core to the relatively high levels of deoxyribonucleotides present in the cytoplasm. This notion is consistent with the observation that simply stripping or permeabilizing the virion membrane with detergents in the presence of deoxyribonucleotides is sufficient to induce DNA synthesis. This may also be at least part of the explanation for the difficulty HIV has in completing reverse transcription and infection in quiescent cells. In some cells, notably cells arrested by starvation, triphosphate levels may be low and limiting for RT, so that addition of exogenous nucleosides can stimulate viral DNA synthesis. But the signal may be more complicated. Conformational changes in the RNA genome at the tRNA primer site may trigger DNA synthesis.³⁷

DNA synthesis can be initiated prematurely during virion assembly and release, such that virion preparations can be shown to contain small amounts of the early DNA intermediates, such as minus-strand strong-stop DNA. In most cases the levels of these DNAs are very low, indicating that only a very small minority of the virion particles have carried out any significant synthesis. However, some circumstances affecting the rate of production and release of virions may enhance this synthesis. In addition, in some particular retroviruses, notably the spumaviruses, substantial DNA synthesis occurs during assembly such that the major form of the genome found in mature virions is a partially or even completely reverse transcribed DNA molecule.^{390,656} These viruses thus resemble the hepadnaviruses more closely than the conventional retroviruses in the relative timing of assembly and reverse transcription.

Steps in Reverse Transcription of the Retroviral Genome

The course of reverse transcription is complex. The reaction can be broken down into a series of discrete steps,²⁰¹ as presented in Figure 47.7.

Formation of Minus-Strand Strong-Stop DNA

The process of reverse transcription is initiated from the paired 3' OH of a primer tRNA annealed to the viral RNA genome at a complementary sequence termed the primer binding site (pbs). DNA is first synthesized from this primer, using the plus strand RNA genome as template, to form minus strand DNA sequences. Synthesis occurs toward the 5' end of the RNA to generate U5 and R sequences. The intermediate formed in this step is termed minus-strand strong-stop DNA. The primer tRNA remains attached to its 5' end.

First Translocation

The next step involves the translocation, or “jump,” of the strong-stop DNA from the 5' to the 3' end of the genome. This translocation requires the degradation of those 5' RNA sequences that were placed in RNA:DNA hybrid form by the formation of strong-stop DNA. The degradation is mediated

FIGURE 47.7. The reverse transcription of the retroviral genome. Thin lines represent RNA; thick lines represent DNA. See text for details. (Drawing courtesy of A. Telesnitsky.)

by the RNase H activity of RT; mutants with altered RNase H activity do not mediate the translocation. This step exposes the ssDNA and facilitates its annealing to the r sequences at the 3' end of the genome.⁹⁵ Normally a full-length strong-stop DNA, synthesized by copying to the 5' cap of the RNA, performs the translocation, though incomplete molecules can jump at low efficiency. The NC protein may facilitate the transfer step. Although there have been reports that jumping is always in *trans*, from one RNA template to the other RNA in the virion, the best evidence is that minus-strand strong-stop jumping goes randomly to either RNA.

Long Minus-Strand DNA Synthesis

The annealing of minus-strand strong-stop DNA recreates a suitable primer-template structure for DNA synthesis, and RT

can now continue to elongate the minus-strand strong-stop DNA to form long minus-strand products. Synthesis ends in the vicinity of the pbs. As the genome enters RNA:DNA hybrid form, the RNA becomes susceptible to RNase H action and is degraded.

Initiation of Plus Strand DNA Synthesis

The primer for plus-strand synthesis is created by the digestion of the genomic RNA by RNase H. A particular short purine-rich sequence near the 3' end of the genome, the polypurine tract or ppt, is relatively resistant to the activity of RNase H. The oligonucleotide remains hybridized to minus strand DNA and serves as the primer for synthesis of plus strand DNA, using minus strand DNA as template. The sequence of the PPT, an unusual structure of the nucleic acid at the PPT, and residues of the RNase H domain of RT have all been implicated in defining the cleavages that form the primer. Sequences upstream of the polypurine tract, an AT-rich region called the T-box, are also important for proper priming. The primer, once it has served to initiate DNA synthesis, is removed from the DNA. Synthesis proceeds toward the 5' end of the minus strand, first copying the U3, R, and U5 sequences, then extending further to copy a portion of the primer tRNA still present at its 5' end. Elongation stops at a modified base normally found at position 19 of the tRNA. The resulting intermediate is termed plus-strand strong-stop DNA.

In some viruses, secondary plus-strand initiation sites are used. There may be multiple RNA primers generated from the RNA genome by the nuclease action of RNase H that can initiate DNA synthesis at dispersed heterogeneous sites. In the case of the lentiviruses and spumaviruses, a second copy of the ppt sequence near the center of the genome is used at high efficiency, and is important for proper completion of reverse transcription.⁹¹

Removal of tRNA

In the next step, the primer tRNA at the 5' end of the minus strand DNA is removed by RNase H. Its removal may occur in two stages: with an initial cleavage near the RNA–DNA junction and a second one within the tRNA. The cleavage need not occur exactly at the RNA–DNA junction, and a single ribonucleotide base (A) is normally left on the 5' terminus of the HIV-1 minus strand without affecting subsequent processes. The posttranscriptional modifications present in natural tRNA are probably important for proper recognition by RT and for plus-strand strong-stop translocation.

The Second Translocation

The removal of tRNA exposes the 3' end of the plus-strand strong-stop DNA to permit its pairing with the 3' end of the msDNA. The sequences anneal via the shared pbs sequences. This annealing forms a circular intermediate, with both 3' termini in a suitable structure for elongation.

Completion of Both Strands

Both strands are now elongated. The final extension of minus strand DNA is coupled to displacement of the plus-strand strong-stop DNA from the 5' end of the minus strand; as minus-strand elongation occurs, the plus-strand strong-stop is peeled away and transferred to the 3' end of the minus

strand. At the end of this elongation, the circle is opened up into a linear DNA. The plus strands are then extended. When multiple plus-strand initiation events have occurred, the completed plus strand will consist of adjacent fragments and contain nicks or discontinuities. Displacement synthesis by an upstream fragment can slowly displace downstream RNAs and DNAs, leading to longer plus strands. However, some nicks or gaps may persist in the final double-stranded product. These breaks may be at heterogeneous positions, though strong sites of plus-strand initiation, such as the one at the central ppt of lentiviruses, can lead to specific sites for such discontinuities. Sequences near the central ppt of the lentiviruses cause termination of synthesis during elongation from upstream primers, ensuring the maintenance of a discontinuity at this site.⁹² This site retains a partially displaced sequence or overlap of a few nucleotides: 99 nt in the case of HIV-1. The structure has been shown to persist even to the time of integration of the DNA into the cell. Host DNA repair processes ultimately correct all such discontinuities.

Although most of the viral DNA is made in the cytoplasm, it may not always be completed in the cytoplasm. For some viruses, completion of the two DNA strands may occur only after entry into the nucleus. Specific mutants with alterations in the Cys-His residues of the NC protein show an interesting phenotype: the formation of linear DNA with heterogeneous and truncated ends.²⁰⁸ These experiments suggest that NC plays a role in the completion, or the stabilization of the ends, of the viral DNA.

A key consequence of the two translocation events that occur during reverse transcription is the duplication of sequences: duplication of U5 during minus-strand strong-stop DNA translocation and of U3 during plus-strand strong-stop DNA translocation. The resulting DNA thus contains two LTRs that have been assembled during reverse transcription. Each LTR consists of the sequence blocks U3-R-U5. The positions of the LTR edges—the left edge of U3, and the right edge of U5—are determined by the sites of initiation of DNA synthesis for the two DNA strands. Thus, the terminal sequences of the complete DNA molecule are also determined by these sites of initiation. These sequences for most viruses are perfect or imperfect inverted repeats, and serve an important role during integration of the DNA (see the Viral *att* sites section).

Biochemistry and Structure of Reverse Transcriptase

The enzyme that mediates the complex series of events outlined in the previous section is RT, one of the most famous of the viral polymerases (25; for review, see 553). All RTs contain two separate activities present in two separate domains: a DNA polymerase able to incorporate deoxyribonucleotides on either an RNA or a DNA template, and an RNase H activity able to degrade RNA only in duplex form. These two activities are responsible for the various steps of reverse transcription. Two distinct domains of the enzyme contain these two activities: an aminoterminal domain contains the DNA polymerase, and a carboxyterminal domain contains the RNase H activity.⁵⁸⁷ While isolated domains can be shown to exhibit either one of the two activities separately, an intact enzyme is required for full activity and specificity. However, the two functions can be provided by two mutant RT molecules so long as they are co-incorporated into a single virion.

DNA Polymerase

DNA polymerase activity is similar to that of all host and viral polymerases in requiring a primer, which can be either RNA or DNA, and a template, which can also be either RNA or DNA. RTs incorporate dXTPs to a growing 3'OH end with release of PP_i, and require divalent cations, usually Mg⁺⁺. The primer must contain a 3'OH end that is paired with the template. RTs cannot perform nick-translation reactions, but they can efficiently perform strand displacement synthesis. The only fundamental way in which RTs are unusual among the DNA polymerases is that they exhibit comparable specific activity on either DNA or RNA templates.

RTs are readily isolated from purified virion particles, and can be even more easily prepared as recombinant proteins expressed in bacteria. RTs are relatively slow DNA polymerases, under standard conditions only incorporating 1 to 100 nucleotides per second, depending on the template. Further, they exhibit poor processivity, and tend to release primer-template frequently *in vitro*. The enzyme must then rebind to the substrate to continue synthesis. Secondary structures in RNA templates can strongly enhance the pausing of RT and its tendency to release from the template.²²⁶ The enzyme also exhibits low fidelity, and though the values of the error rate vary widely with the primer, template and type of assay, the misincorporation rate of most RTs under physiologic conditions is on the order of 10⁻⁴ errors per base incorporated. This rate suggests that during replication there would be approximately one mutation per genome per reverse transcription cycle. The mutation rate observed *in vivo* is roughly consistent with this high error rate, though fidelity *in vivo* may be somewhat better than *in vitro*. Drug-resistant variants that do not incorporate chain-terminating analogs are often found to exhibit higher fidelity, perhaps because they require a more precise fit for the correct incoming triphosphate to allow for discrimination against the analog. A wide range of types of mutations are created by RT errors, and both the type and the frequency of appearance of each type of mutation exhibit a complex dependence on sequences and structures in the template.

RTs do not generally exhibit a proofreading nuclease activity,³⁵ and misincorporated bases are not removed as efficiently by most RTs as they are by host DNA polymerases. However, mutants of the HIV-1 RT resistant to AZT have been shown to exhibit an enhanced ability to remove the incorporated AZT moiety at the 3' end through a pyrophosphorolysis reaction.³⁸² Thus, it is possible for RT to remove some such analogs and rescue a terminated chain for continued elongation.

RNase H

The RNase H activity of RT is an endonuclease that releases oligonucleotides with a 3'OH and a 5'PO₄. This property allows the products of RNase H action to serve as primers for initiation of DNA synthesis by the DNA polymerase function of RT. There is an obligate requirement that the RNA be in duplex form, normally an RNA–DNA hybrid. However, retroviral RTs are also able to degrade RNA–RNA duplexes, an activity termed RNaseH*.²⁴³ The RNase H enzyme is capable of acting on the RNA of a template in concert with the polymerase as it moves along a nucleic acid, and as it does so its active site is located about 17 to 18 bp behind the growing 3' end.²⁰⁶ RNase H can also act independently of polymerization. All RNase H activity requires a divalent cation.

Subunit Structures

RT is incorporated into the virion particle during assembly in the form of a large Gag-Pol precursor (see below), and is released by proteolytic processing of the precursor during virion maturation. Different viruses make somewhat different cleavages in the precursor, and thus the RTs exhibit several different subunit structures (see below). In the gammaretroviruses, RT is a simple monomer in solution, corresponding only to the aminoterminal DNA polymerase and the carboxyterminal RNase H domains. These two domains can be expressed separately, and the isolated proteins exhibit their respective activities,⁵⁸⁷ though the specificity of the RNase H is affected by this separation. In the avian viruses, the RT is present as an $\alpha\beta$ heterodimer, comprised of a smaller subunit containing the DNA polymerase and RNase H domains; and a larger β subunit containing these two domains but also retaining the integrase domain. In the lentiviruses, RT is again a heterodimer with a larger subunit (p66) containing the DNA polymerase and RNase H domains, and a smaller subunit (p51) lacking RNase H. The properties of the different enzymes as DNA polymerases are very similar in spite of these different subunit structures, and thus the significance of these various compositions for RT function is unclear. A curious observation was made that some RT inhibitors—the so-called nonnucleoside RT inhibitors—can potentially enhance the association of p66 and p51, locking them into an inactive dimer.⁵⁸⁰

Crystal Structures

The three-dimensional structure of a number of RTs have been determined by X-ray crystallographic studies. Structures of the unliganded HIV-1 RT,^{246,515} RT bound to nonnucleoside RT inhibitors,^{127,135,300,504} RT bound to an RNA pseudoknot inhibitor,²⁶⁰ RT bound to a duplex oligonucleotide,^{17,248,258,259} and RT bound to a polypurine tract RNA:DNA hybrid,⁵³¹ as well as the isolated RNase H domain,¹²⁸ have all been reported. The two subunits are folded very differently so that the overall structure is highly asymmetric. The structure of the p66 is similar to that of a right hand, with fingers, palm, and thumb domains named on the basis of their position in the structure (Fig. 47.8). The nucleic acid lies in the grip of the hand, held

by the fingers and thumb. The YXDD motif present at the active site for the DNA polymerase lies at the base of the palm. The RNase H domain is attached to the hand at the wrist. The p51 subunit, while made up of the same domains as the aminoterminal part of p66, is folded differently and lies under the hand, not making direct contact to the nucleic acid and thus not thought to participate in chemistry. The structure of p66 with and without a liganded nucleic acid is very different, with the thumb domain flexing to allow substrate binding. A surprising aspect of the structures is that the nucleic acid helix can be highly bent, perhaps accounting for the enzyme's ability to sense conformationally strained substrates.⁵³¹ Theoretical considerations suggest that the thumb may move during elongation.

Structures of the fingers and palm subdomain and of the complete Moloney MuLV RT at very high resolution have also been determined.^{126,200} The monomeric protein is broadly similar to the p66 subunit of HIV-1 RT.

Inhibitors

RT is a major target of antiviral drugs useful in the treatment of retroviral diseases such as AIDS. All such drugs used to date are inhibitors of the DNA polymerase activity of RT, and fall into two classes: nucleoside analog inhibitors (chain terminators), and nonnucleoside RT inhibitors (NNRTIs). The nucleoside analogs are typically prodrugs, and need to be activated by phosphorylation to the triphosphate form. These are then incorporated by RT into the growing chain, and serve to block further elongation. Examples include AZT, ddC, ddI, d4T, and 3TC. The NNRTIs are a group of compounds that are structurally diverse, but nevertheless interact with a common binding pocket in RT to prevent its normal activity.⁶⁰⁰ There are indications that the binding may inhibit the enzyme's flexibility. For both classes of inhibitors, monotherapy with a single drug selects for drug-resistant variants that quickly predominate in the virus population, and for each drug, a pattern of mutations has been identified that serves to indicate the appearance of drug resistance.³¹⁵ In many cases these mutations alter the binding side for the nucleoside or NNRTI such that the drug cannot bind and therefore cannot inhibit the enzyme. In the case of AZT, however, the mutations do

FIGURE 47.8. Schematic image of the heterodimeric reverse transcriptase (RT) of human immunodeficiency virus type 1 (HIV-1), showing the p66 (top, dark gray) and p51 (bottom, light gray) subunits. The molecule is arranged in the conventional orientation to show its similarity to the human right hand, palm up. Fingers, thumb, palm, connection, and RNase H domains of each subunit are indicated. An RNA template strand (thin line) and a DNA primer strand (heavy line) are modeled into the polymerase (Pol) and RNase H (RH) active sites.

not prevent the binding and incorporation of AZTTP into the growing chain, but rather seem to activate a reverse reaction in which the AZT nucleotide is removed from the chain, subsequently permitting normal elongation.³⁸² Combination therapy, typically involving the simultaneous treatment with three different drugs, can suppress virus replication to such an extent that variants resistant to all the drugs do not appear, at least for months or years.

RECOMBINATION

The process of reverse transcription could in principle take place using a single template RNA molecule. In fact, however, retrovirions contain two copies of the RNA genome co-packaged into one particle, and the course of reverse transcription typically makes use of both RNAs.^{247,573} **Recombination occurs between homologous sequences in the two RNAs, happening at surprisingly high frequencies, more than once per replication event per genome on average.**^{511,667} Normally the two RNAs in a virion are identical, so that homologous recombination events are invisible and without consequence. When the two RNAs are distinct, however, as when they derive from two viruses or viral strains, the result is a very high frequency of recombination between them among the resulting proviral DNAs. Thus, physical markers and genetic markers recombine rapidly whenever the two genomes are co-packaged into one virion and thus are co-extant during a single round of reverse transcription. The frequency is highly dependent on the sequence and structure of the RNA in the region undergoing recombination. Similar recombination does not occur at high frequency when cells are co-infected simultaneously with two separate virus preparations, suggesting that each incoming virus particle performs its own reverse transcription reaction in the cytoplasm in *cis*, and does not freely exchange RNAs with other reactions happening in the same cell.

Models for Recombination

Two mechanisms provide for recombination between two genomes. In one, the copy choice model, recombination occurs during minus-strand synthesis. As RT proceeds along an RNA, it has the potential to carry out a template switch in which an incomplete DNA copied from one template serves to prime further elongation on the other RNA molecule.^{351,465} Pausing may enhance this transfer, and secondary structures in the RNA may act as hot spots for such recombination. Breaks in the RNA genome, which may be encountered often, cause a “forced copy choice”: transfer to the other RNA. This rescues an otherwise dead virus, and may represent the major evolutionary basis for high-frequency recombination in the viruses. The RNase H activity of RT may help release an incomplete DNA, promoting its serving as primer on the new template; NC also facilitates the reaction.⁴¹³ This mechanism is likely the more important one of the two.⁶⁶⁶

In the other mechanism, strand-displacement assimilation, recombination occurs when at least portions of two minus strands have been synthesized in one virion. While multiple plus-strand fragments are elongating on one minus-strand template, strand displacement can expose the 5′ end of such fragments, which can then pair with the other minus-strand DNA to form a bridged “H” structure as intermediate. Further

synthesis and repair of these structures leads to the transfer of sequences to the new DNA.²⁷⁴

When a recombination event occurs, there is a nonrandom increase in the probability that another recombination will occur nearby, a phenomenon called negative interference. This suggests that RT or the genomes may become recombination prone at specific times. When multiple recombination events occur, the resulting DNA is a patchwork of the sequences derived from the two input RNAs.

The translocation of the two strong-stop DNAs provides a special opportunity for recombination between the two viral genomes. When the minus-strand strong-stop DNA is formed, it has the potential to translocate from the 5′ end of its template to the 3′ end of either RNA molecule; though this event has been reported to occur strictly in *cis*, or strictly in *trans*, it most likely occurs randomly. Similarly, when plus-strand strong-stop DNA is formed, it too could in principle translocate to the 3′ of either minus strand. However, this translocation seems most often to occur in *cis*, perhaps simply because the frequency with which two long minus-strand DNAs are successfully formed, and thus are available to serve as acceptors, is low.

Recombination between two RNAs during reverse transcription can also occur between nonhomologous sites at lower frequency. Reconstructions suggest that these events are perhaps 100 to 1000 times less frequent than homologous recombination. These events can result in duplications or deletions in the DNA product of the reaction. Furthermore, if nonviral RNAs or chimeric RNAs containing viral and nonviral sequences are packaged into virions, such nonhomologous recombination events can create new joints and link a viral sequence to the nonviral sequences. These events are thought to play a central role in the process of transduction of cellular genes, most importantly during the formation of acute oncogenic retroviral genomes (see below).

INTEGRATION OF PROVIRAL DNA

The integration of linear retroviral DNA, like reverse transcription, is a crucial and defining feature of the retroviral life cycle. Integration is required for efficient replication of most retroviruses; mutants that are unable to integrate do not establish a spreading infection. The orderly and efficient integration of viral DNA is unique to the retroviruses. Although infection by some DNA viruses can result in the integration of viral DNA fragments into the host genome at low efficiency, these events are not the result of specific viral functions. Further, the establishment of the integrated provirus is responsible for much of retroviral biology. It accounts for the ability of the viruses to persist in the infected cell; for their ability to permanently enter the germ line; and for the mutagenic and oncogenic activities of the leukemia viruses. It also establishes a reservoir of latently infected cells in AIDS patients that resists antiviral drug therapy and that can be reactivated to induce virus replication.

Once the provirus is established, the DNA is permanently incorporated into the genome of the infected cell. There is no mechanism by which it can be efficiently eliminated. At very low frequencies, homologous recombination between the two LTRs can delete most of the provirus, but even here a single (“solo”) LTR remains.⁶⁰⁹ As the host cell divides, the provirus is transmitted to daughter cells as a new Mendelian locus. Thus,

it is likely to persist in the cell for its normal life span and to convert the cell permanently to a chronic producer of progeny virus.

Unintegrated DNA Forms

The product of the reverse transcription reaction, as outlined in the previous section, is a full-length double-stranded linear DNA version of the genome, flanked at each end by copies of the LTR. The next step is the movement of the DNA into the nucleus, and the appearance two new DNA forms: closed circular molecules containing either one or two tandem copies of the LTR (Fig. 47.9). A small amount of the one-LTR circle may be formed during reverse transcription (see the Steps in reverse transcription of the retroviral genome section), but the bulk is thought to be formed by homologous recombination between the two LTRs of the linear DNA. The tandem two-LTR circles are apparently formed by the blunt-end ligation of the termini of the linear DNA. This event creates a unique sequence, termed the LTR–LTR junction, that is often used as a hallmark of nuclear entry of the viral DNA. The joints are often imperfect, with loss of nucleotides from one or both termini at the joint.^{556,626} There are also some circles that arise by autointegration of the ends of

the linear DNA into internal sites, forming DNAs with deletions or inversions⁵⁵¹; these circles are generally nonfunctional in terms of generating progeny virus.

Since three distinct unintegrated DNA form—one linear and two circular—coexist in the nucleus, it was uncertain for many years which form might serve as the precursor for establishment of the integrated provirus. In spite of prejudices based on such precedents as phage lambda, it is now clear that circles are not efficient substrates in the integration reaction and that the immediate precursor for the integration reaction is the linear duplex DNA. The circles are apparently dead-end products of a side reaction, formed by host enzymes acting on linear DNAs that have failed to integrate. There are settings and cell types in which unintegrated viral DNAs are observed to accumulate to high levels; various tissues in human HIV disease show considerable circular DNAs. While this DNA may reflect some unusual processing of the DNA, much of it is probably formed simply by massive infection occurring shortly before the DNA is harvested.

Unintegrated DNA is not a good substrate for forward transcription,⁵²⁷ perhaps because it is still retained in a complex that is poorly accessible to RNA polymerase. Mutant viruses that cannot integrate are unable to establish an efficient spreading infection, although low levels of virus can be produced.⁵⁴¹ A very small subset of cells infected with such integration-defective mutants do integrate viral sequences through nonviral means, creating oligomeric tandem repeats similar to those formed after naked DNA-mediated transformation.²²²

FIGURE 47.9. Unintegrated DNA structures formed after retroviral infection. The incoming RNA genome (*top*) is converted by RT to a double-stranded linear DNA containing two LTRs (*boxes*) in the cytoplasm. The termini of the DNA consist of short, inverted repeats, and always contain a conserved CA dinucleotide near the 3' ends; the 3' terminal sequences of the MLVs (CATT) are shown. The linear DNA is then localized to the nucleus, and two circular double-stranded DNAs are formed: a circle containing one LTR, and a circle containing two tandem LTRs. The LTR–LTR junction contains a unique inverted repeat sequence.

Entry into the Nucleus

A key step that must take place before integration can occur is the entry of viral DNA into the nucleus. The mechanisms of nuclear entry are largely unknown, but there are probably at least two distinct routes used by different retroviruses. Simple retroviruses show a profound requirement for passage through mitosis for successful establishment of the integrated provirus,^{326,385,517,608} and the block in nondividing cells is at or close to the step of nuclear entry. Tests of the state of the viral DNA in nondividing cells are consistent with the notion that the pre-integration complex must await the breakdown of the nuclear membrane in order to have access to the cellular DNA. Infection of nondividing cells results in the accumulation of linear dsDNA in the cytoplasm, and no further signs of infection. The viral DNA will persist in the cell for some time, and if the cell is stimulated to undergo division, the viral DNA will integrate and infection will proceed. However, the DNA loses its capacity to become activated in this way fairly rapidly.^{15,385} Some simple retroviruses are not strongly dependent on mitosis,²²⁸ and some postmitotic cell types may be susceptible to infection.³³⁸ For many viruses the restriction is quantitatively very significant, and profoundly limits the utility of simple retroviral vectors for gene therapy.

In contrast, lentiviruses and spumaviruses are able to successfully infect nondividing cells, suggesting that there must be an active transport of viral DNA through an intact nuclear membrane.^{77,325,326,409,623} This capability has made lentiviruses very attractive as gene delivery vectors for gene therapy applications. The molecular basis for this capability is a subject of great controversy. The lentiviral MA protein has been argued as essential for the infection of nondividing cells, and the phosphorylation of MA has been argued as necessary to promote

dissociation from the membrane and allow nuclear import, but these findings were discounted in later studies. Similarly, it has been shown that the Vpr protein is present in the preintegration complex, and can bind to nucleoporin components that may mediate nuclear import. DNA structures present at the second internal copy of the polypurine tract have also been suggested as important for infection of nondividing cells, but this notion has also been discounted. Another attractive model is that the IN protein might be involved in the nuclear import of the complex. IN itself contains nuclear localization signals that can function to target ectopically expressed IN to the nucleus, but these seem not to mediate PIC nuclear import or nuclear retention.

Recent experiments suggest that the CA protein of the incoming PIC may define competence for nuclear import.⁶⁴⁶ The lentiviral CA may serve to deliver the PIC to particular Nups, nuclear pore components, to initiate import. Studies of HIV-1 mutants with single changes in CA suggest that PICs can be imported via either of two alternative pathways, with wild-type virus using Nup153 and TNP03, and the N74D mutant using Nup155.^{99,306,320} Other studies have implicated Nup98 in HIV-1 PIC entry into the nucleus.¹⁵¹ Another study of import *in vitro* has suggested that a specific importer protein, importin 7, is required for PIC entry,^{167,661} though this has been disputed.⁶⁷² Fractionation of extracts using similar *in vitro* import assays showed, remarkably, that tRNAs can promote uptake of PICs into nuclei.⁶⁶² Whether tRNAs mediate import *in vivo* remains uncertain.

Foamy viruses may have a distinctive route of nuclear entry involving microtubular transport by dynein and centrisomal association, but the mechanism is not yet well understood.^{474,526}

Structure of the Provirus

An important aspect of retroviral integration that distinguishes the process from nonviral or other viral mechanisms of DNA integration is the fact that the insertions create a consistent provirus structure. The integrated provirus is collinear with the product of reverse transcription, and consists of a 5' LTR, the intervening viral sequences, and a 3' LTR, inserted cleanly into host sequences. The joints between host and viral DNA are always at the same sites, very near the edges of the viral LTRs. As compared to the unintegrated linear DNA, there is a loss of a small number of base pairs, usually two, from each terminus of the viral DNA. There is also a duplication of a small number of base pairs of host DNA initially present once at the site of insertion that flank the provirus (Fig. 47.10). The number of

base pairs duplicated is characteristic of each virus, and ranges from 4 to 6 bp.

Biochemistry of Integration

The actual integration of viral DNA into a target is mediated *in vivo* by the viral integrase protein IN,^{450,495,541} which is brought into the cell inside the virion, and acts to insert the linear DNA into the host chromosome. Some aspects of IN function have been studied by analysis of viral DNA formed *in vivo*.⁵²¹ Most of our understanding of IN function, however, has been obtained through analysis of *in vitro* integration reactions, first using complexes extracted from infected cells,^{74,186} and later using recombinant IN protein. The reaction proceeds in two steps: 3' end processing and strand transfer. A schematic view of these reactions is shown in Figure 47.11.

3' End Processing

In the first step, the two terminal nucleotides at the 3' ends of the blunt-ended linear DNA are removed by the integrase to produce recessed 3' ends and correspondingly protruding 5' ends. This cleavage occurs endonucleolytically at a highly conserved CA sequence, and releases a dinucleotide. For most viruses the terminal sequence is such that a TT dinucleotide is released, though this rule has exceptions. The ends do not remain covalently bound to protein, and the energy of the hydrolyzed phosphodiester bond is not retained.

Strand Transfer

In the second step, the 3'OH ends created by processing are used in a strand transfer reaction to attack the phosphodiester bonds of the target DNA.¹⁸⁶ The attack occurs by an Sn2-type reaction, with inversion of the phosphorus center as detected with chiral labeling of the phosphate.¹⁵⁸ The formation of the new phosphodiester bond between the viral end and host DNA displaces one of the phosphodiester bonds in the host DNA, leaving a nick. The protruding 5' end of the viral DNA is not joined to the host DNA by IN. The reaction is a direct transesterification, and thus no ATP or other energy source is required. Mutational studies strongly suggest that the two activities—processing and joining—utilize the same active site residues. In fact, the two steps involve similar chemistry: 3' end processing is an attack on DNA by a hydroxyl residue of water, while joining is an attack on DNA by a 3' hydroxyl residue of another DNA. It should be noted that other hydroxyl residues can participate; alcohols such as glycerol can be utilized, and

FIGURE 47.10. Integration of the viral DNA to form the provirus. The precursor for the formation of the provirus is a linear double-stranded DNA containing two LTRs (boxes) and with inverted repeat sequences at the termini. The target site in the host DNA is indicated by the arbitrary sequence block denoted 12345. Integration occurs by joining the 3' CA dinucleotides near the termini to the target DNA. The reaction is associated with loss of two base pairs at the termini of the viral DNA, and with duplication of a small number of base pairs (5 shown here) initially present only once in the target DNA.

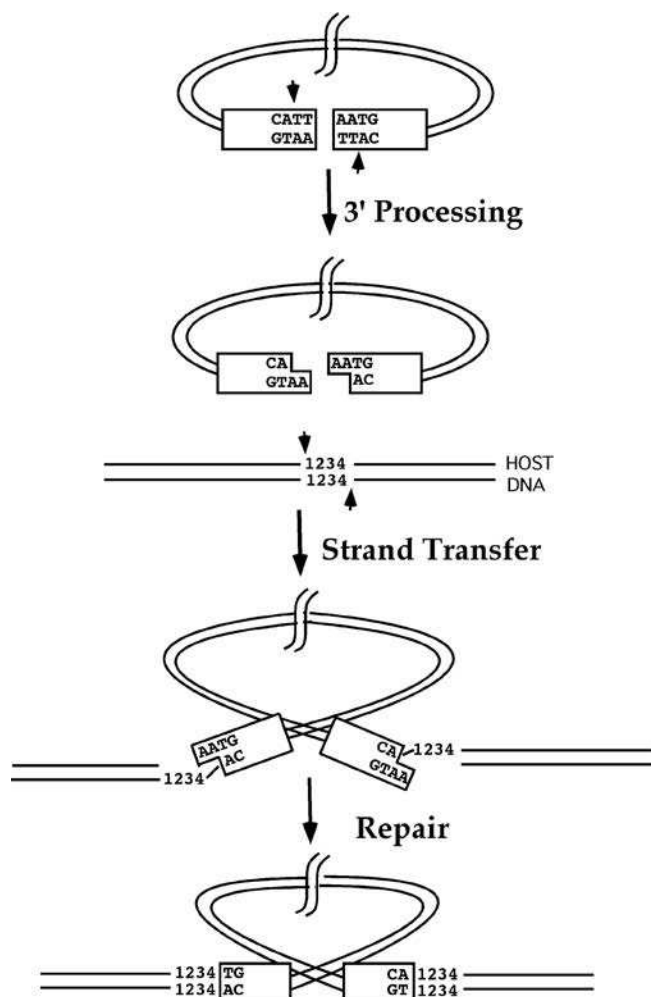

FIGURE 47.11. Steps in the integration of the viral DNA. The full-length linear DNA (top) is processed by the viral integrase with the endonucleolytic removal of dinucleotides at the 3' termini. The resulting DNA is then used in a strand transfer reaction in which the 3' OH ends attack phosphodiester bonds of the target site DNA to make staggered breaks in the two strands. The resulting gapped intermediate is subsequently repaired by host enzymes.

the 3'OH of a DNA can even attack a phosphodiester bond on the same DNA, forming a cyclic product.¹⁵⁸

Disintegration

The IN protein exhibits a third enzymatic activity *in vitro*: a reversal of the integration reaction known as disintegration.⁹⁸ This activity releases DNA from a branched structure and seals the nick at the site of the branch. The significance of the activity *in vivo* is uncertain.

Target Site Duplication

In a wild-type virus, when the two ends are joined to the two strands of the target DNA, the two sites of attack are staggered by a few base pairs. After the joining, the resulting structure contains short gaps in the host DNA and unpaired bases from each 5' end of the viral DNA. The 5' ends of the viral DNA are not joined to host DNA by any known activities of IN.

However, the 5' ends are very quickly repaired *in vivo*, almost as quickly as the initial integration reaction.⁵¹⁶ These discontinuities are presumed to be repaired by the host repair enzymes, though it is possible that the viral RT or IN could participate. The processing and filling in the gaps creates a short duplication of sequence that was present only once at the target site; these duplications flank the integrated provirus. The number of bases duplicated is characteristic of each virus. Thus, the murine and feline viruses cause a 4-bp duplication, HIV-1 causes a 5-bp duplication, and the avian viruses cause a 6-bp duplication.

Viral *att* Sites

The sequences at the termini of the viral DNA, the *att* sites, are recognized by the viral IN protein and are important for end processing and joining.^{79,104,109,610} These terminal sequences are imperfect inverted repeats. The most conserved residues are a CA dinucleotide pair that lies near the 3' terminus and determines the site of 3' processing. Sequences upstream from the CA for perhaps 10 to 12 bp are needed for efficient integration, but these sequences are different for different viruses, with no indication of broadly conserved sequence motifs. Since the two termini of any given virus are somewhat different, they usually show differential efficiency of utilization in various assays. The fact that two distinct ends are bound together in a complex may be important for the concerted integration of these ends into the target.⁶¹⁵

The sequence-specific binding to the *att* site is probably performed by the core domain of IN. The nonspecific DNA binding activity of IN has made it difficult to detect sequence-specific binding to these regions, though under some conditions preferential binding to the authentic sequences can be demonstrated.¹⁶¹ The observation that an IN mutation can compensate for a mutation in the DNA termini provides evidence for the delicate interaction between IN and the DNA termini.

Both 3' processing and strand transfer reactions are concerted reactions *in vivo*. The processing step occurs simultaneously at both termini of the viral DNA and requires the correct sequences at both termini. Thus, a mutation altering the sequence at one end of the viral DNA of MuLV blocks the processing reaction at both ends.⁴⁰⁵ This result suggests strongly that the reaction requires both termini to be loaded into a complex before hydrolysis proceeds. Similarly, the strand transfer reaction normally occurs so that both ends are joined to the target DNA, and at a fixed spacing between the two sites along the DNA helix. The 3' processing and strand transfer reactions can both be carried out *in vitro* using native PICs, extracted from recently infected cells, and these reactions reconstruct the concerted nature of the *in vivo* reactions. Alternatively, integration can be performed using artificial DNA constructs and recombinant IN protein. However, these systems typically only mediate a half-reaction: that is, the uncoupled processing of one viral terminus and its joining into a single target DNA. Efforts have led to the identification of conditions and factors that mediate formation of a complex and that enhance concerted joining.^{7,175,616} Once such a protein–nucleic acid complex is formed, it is very stable.

Structure of the Integrase

The IN protein consists of three distinct domains: an N-terminal region containing an HHCC zinc-finger motif; a

central catalytic core containing the so-called D,D-35-E motif; and a less well-conserved C-terminal region. The IN protein is a multimer: it readily dimerizes, and at high concentration forms tetramers as well. All three regions may be involved in the multimerization of IN and in DNA binding. Many of the residues important for enzymatic activities have been identified by mutagenesis. The most crucial residues for catalysis are the acidic amino acids in the D,D-35-E motif, a highly conserved array of three residues in the core region of many integrases and transposases.³⁰⁸ Mutants indicate that both the N- and C-terminus are also important for function. Surprisingly, pairs of IN mutants with alterations in different regions of the molecule can often complement to restore normal function. The separate N-terminal domain can even complement a nonoverlapping fragment, suggesting that these domains can still co-assemble into a functional oligomeric complex.

Early X-ray crystallography work first defined the structures of the HIV-1 and avian virus IN core domains, and NMR methods defined the structures of the N- and C-terminal domains. Very recently a crystal structure of the complete integrase from a foamy virus in complex with a model target DNA oligonucleotide has been obtained.³⁵⁹ This structure reveals a tetramer, arranged as a dimer of dimers, holding the target

DNA in a strongly bent conformation. The catalytic sites for strand transfer are nicely positioned to hold the viral DNA termini for attack of the target DNA (Fig. 47.12).

Preintegration Complex

Integrase does not normally act alone; a large complex of proteins and nucleic acid is responsible for mediating the formation of the provirus *in vivo*.^{66,94} The nature and components of the preintegration complex (PIC), or intasome, are not known in any detail for either the simple or the complex viruses. The PICs of the simple gammaretroviruses contain p12, CA, RT, and IN, but other viral proteins may be present.^{66,489} The PICs of the complex viruses contain only lower levels of CA, but contain MA, NC, Vpr, RT, and IN.³⁸⁸ Thus, the PICs of the complex viruses may be very different from those of the simple viruses, consistent with their distinctive ability to infect nondividing cells.^{165,166} Many of these proteins probably stay with the DNA even after entry into the nucleus. The PICs contain a large structure protecting the two ends of the DNA, and perhaps holding them in proximity. The formation of this structure, detected as a footprint in a modified nuclease sensitivity assay,⁶²¹ requires both IN and the correct sequences at the termini of the DNA.⁶²²

Domains are indicated: NTD, N-terminal domain; NED, NTD extension domain; CTD, C-terminal domain; CCD, catalytic core domain. *Bottom*, Ribbon diagram of protein. Position of domains, target DNA (tDNA) and modeled viral DNAs (vDNA) are indicated. (Courtesy of Peter Cherepanov, Division of Infectious Diseases, Imperial College London, London, UK.)

Host Proteins and Integration

A number of host proteins have been identified as potentially involved in the establishment of the provirus. One such protein is BAF-1, a low-molecular-weight protein recovered from the MuLV PIC for its ability to inhibit autointegration of the LTR edges into internal sites in the viral DNA.³²¹ By inhibiting this reaction, BAF-1 can enhance normal integration into target DNAs in *trans*. However, infection of BAF-1-deficient cells occurs normally, suggesting that BAF-1 is not an essential player in the early events of the viral life cycle. Another such partner is LEDGF (lens epithelial-derived growth factor, a misnomer), a nuclear protein of uncertain function, which binds directly to the HIV-1 IN and dramatically enhances its integration activity.^{96,339,358}

The integration of retroviral DNA has been shown to activate an apoptotic program in cells deficient in DNA-stimulated protein kinase (DNA-PK), an enzyme implicated in the DNA damage response¹²⁵; the related kinase ATR and other components of the nonhomologous end joining repair machinery may also be involved.^{123,124} While it is not clear whether these kinases play any direct role in integration, they are likely involved in sensing the products of active integrase and responding to the damage. Their absence leads to substantial cell death in cells taking up the PIC.

Distribution of Integration Sites

An important issue affecting the ability of the retroviruses to create mutations is the distribution of integration sites in the host genome. Proviruses are inserted at very approximately random locations in the genome, and thus have the opportunity to create mutations in any gene. Various studies, however, have uncovered significant deviations from a completely random distribution. At the sequence level, examination of large numbers of integration sites has revealed weak but statistically highly significant preferences for symmetrical target sequences.^{212,240,643} Large-scale surveys of thousands of integration sites cloned from pools of infected cells have allowed analysis of the frequency of insertions into the 5' upstream regions of genes, into transcribed regions, and into nontranscribed regions. The results show that different viruses show distinct biases for their target sites.^{30,389,535,642} HIV-1 tends to insert into transcribed regions, more or less equally along such regions; MuLV tends to selectively insert its DNA in sequences upstream from the 5' end of transcribed regions, near transcriptional start sites; ASLV shows only very weak preference for active genes and none for 5' regions. Activation of transcription *per se* can apparently, in some circumstances, inhibit avian retroviral integration at specific genes.³⁷² These studies collectively show that various retroviruses have evolved mechanisms to choose aspects of their integration sites, presumably in support of their chosen life styles during infection. The biases are presumably determined largely by their respective IN proteins, but could also involve other viral proteins.

EXPRESSION OF VIRAL RNAs

The integration of the provirus signals a dramatic change in the life style of retroviruses; it marks the end of the early phase of the life cycle and the beginning of the late phase. The early phase is driven by viral enzymes performing abnormal events such as reverse transcription and DNA integration, while the

late phase is mediated by host enzymes performing such relatively normal processes as transcription and translation. This late phase of gene expression may begin immediately with the synthesis of viral RNAs and proteins, and the assembly of progeny virions (see Fig. 47.13 for an overview). For many viruses, the transcriptional promoters that drive this expression are constitutively active and cause the production of virions in a relatively unregulated way. In other viruses the activity of the promoter may be regulated, either by viral or host factors. The basic phenomenology of proviral gene expression will be reviewed, and the regulation exhibited by the complex retroviruses will be mentioned briefly.

Overview of Viral RNA Synthesis

The synthesis of viral RNA from viral DNA leads to the formation of a long primary transcript, which is then processed and may be spliced to form a small number of stable transcripts. The U3 region of the LTR contains a promoter recognized by the RNA polymerase II system; these sequences direct the initiation of transcription starting at the U3-R border. Cellular machinery then caps the 5' end of the RNA with m7G5'ppp5'G_mp. The first G residue after the cap is a templated base in the provirus. Transcription proceeds through the genome, and continues through the 3' LTR and into the downstream flanking host DNA. Finally, the RNA is cleaved and polyadenylated at the R-U5 border of the 3' LTR, generating a complete, unspliced viral genomic RNA suitable for incorporation into the virion particle. Most genomes contain an AAUAAA sequence acting as the signal for this 3' processing. The sequence normally lies in the R region, but the complete sequence needed for recognition can be complex, lying upstream or downstream, and may even be discontinuous, brought together by RNA folding to create the functional signal. The exact site of polyadenylation is not critical for virus replication; mutants in which the polyadenylation signal is inactivated generate longer RNAs that extend into downstream flanking sequences.⁶⁶⁸ These RNAs very efficiently mediate normal replication.⁵⁷⁸ A subset of the RNA is spliced to give rise to one or more subgenomic RNAs. The patterns of spliced mRNAs can be simple or exceedingly complex. Both the unspliced and spliced RNAs are then exported from the nucleus for translation.

Initiation of Transcription

The efficiency of initiation of transcription at the 5' LTR is the major determinant of the levels of viral RNA formed in the cell. The promoter in the LTR is typically a very potent one, and the levels of viral RNA are often constitutively high. However, the cell type, the physiologic state, and the integration site¹⁶⁹ can all result in substantial variation in the efficiency of transcription. In some viruses, the promoter is not constitutively active but depends on the activity of specific transcription factors such as the glucocorticoid receptors.

Positive Regulatory Elements in U3

The transcriptional elements in the U3 region of the simple viruses contain both core promoter sequences and enhancers. The core promoters contain a TATA box, bound by TFIIB; a CCAAT box, bound by CEBP⁵²⁵; and sometimes an initiator sequence near the U3-R border. The U3 regions of even closely related retroviruses are very diverse, and can evolve rapidly during viral replication. The enhancers are similar to those found

FIGURE 47.13. The late stages of the retroviral life cycle. The integrated provirus is used as the template (*top*) for the expression of viral RNAs. A subset of the transcripts are spliced, and the unspliced and spliced mRNAs are exported to the cytoplasm. The unspliced RNA is used to make Gag and Gag-Pol proteins, and also serves as the genome; spliced mRNA is used to make Env proteins. The proteins and RNA associate under the membrane to form the budding progeny virion.

in many host promoters in containing multiple short-sequence motifs, arranged in very close packing; often there are tandemly repeated copies of some of these motifs. These short sequences are the binding sites for a large number of host factors that regulate transcription (e.g., see 562). Different cells and cell types will make use of distinct arrays of these factors to mediate transcription from a given viral LTR.²¹³ The factors are not simply additive but may interact in complex ways on particular viral sequences. A partial list of these factors used by various retrovirus LTRs includes: Sp1; USF-1; the Ets family of factors, which include more than 20 members in vertebrates; the core-binding factor (CBF), consisting of an α - β heterodimer; nuclear factor 1 (NF1); and a mammalian type C retrovirus enhancer factor (MCREF-1). Specific viruses may often contain recognition sites for other more specific positive regulatory factors. Major examples of such factors include the glucocorticoid receptors, driving expression of the MMTV genome, and to a much lesser extent, other MuLVs; NF- κ B, important for expression from the HIV-1 LTR in certain cell types; the GATA factors for Cas-BR-E and other viruses; and the myb

protein. Evidence has been obtained that the STAT factors, DNA binding proteins normally activated the Janus kinases (Jaks) may also be important for MMTV transcription.⁴⁹³

Negative Regulatory Elements

A number of negative regulatory factors that reduce viral expression have been identified. Embryonic carcinoma cells, and true embryonic cells, are the best-characterized examples of cell types that strongly repress LTR-mediated transcription through expression of negative regulatory proteins. The MuLVs are silenced via a stem-cell specific repressor that binds to a site, curiously, overlapping almost perfectly with the proline tRNA primer binding site.^{289,473} The proteins responsible for this silencing in mouse embryonic stem cells have recently been identified as TRIM28 (Kap-1) and the zinc-finger protein ZFP809.^{637,638} Viruses that use an alternate primer tRNA and thus lack the pbs recognition site for these proteins can escape the repression.²³⁹ Other negative factors include one known variously as UCRBP, NF-E1, or YY1,¹⁷⁶ and a cellular embryonal LTR-binding protein (ELP; 598).

trans-Acting Viral Regulatory Factors

The complex retroviruses encode an array of small regulatory proteins that can activate transcription from the viral LTR in *trans*. Examples of these transactivators include the HTLV-1 Tax protein¹³² and the HIV-1 Tat protein.¹²⁰ The Tax protein acts in concert with a complex of host proteins, the activating transcription factor/CRE-binding protein (ATF/CREB), and binds to three cAMP response elements in the viral LTR. Tax thus sets up a positive feedback loop that results in high levels of viral transcripts. The Tat protein is unusual among transcriptional activators in that it binds to a structure in the 5' end of nascent viral RNA, rather than to DNA.^{136,548} Tat binds to a bulged hairpin structure, the TAR element, and recruits a pair of host proteins, cyclinT/cdk9, to the RNA. These proteins enhance the ability of RNA polymerase to elongate beyond the LTR and down the genome with high processivity, probably by phosphorylation of the C-terminal repeat domain (CTD) of the polymerase. Again, the result is a strong positive feedback loop that results in high levels of viral RNA. (For more detailed discussion of *tat* function, see 120, and Chapter 49 of this book.)

Beginning and Ending the RNA

Because proviruses contain two identical LTRs, transcription can be initiated at both 5' LTR and 3' LTR. However, the 5' LTR is generally much more efficiently utilized than the 3' LTR.²³⁵ One possible mechanism is promoter interference, in which the upstream promoter being active suppresses the utilization of the downstream promoter. It is possible that elements near the 3' LTR may restrict use of the downstream LTR, so that generally transcripts initiating at the 5' LTR predominate. These restraints may be lost in tumors, in which transcription from the 3' LTR can be significantly enhanced.⁵⁹ Similarly, since there are two LTRs, transcripts might in principle be subject to 3' end processing at either the 5' LTR or the 3' LTR, but most of the RNAs formed extend from the 5' LTR to the 3' LTR.

RNA Processing

The full-length transcript of the retroviral genome is directed into several pathways. A portion of the transcripts is exported directly from the nucleus and serves as the genome to be packaged into the progeny virion particle, assembling either at the plasma membrane or in the cytoplasm. Another portion with identical structure is also exported and used for translation to form the Gag and Gag-Pol polyproteins. It is not yet clear if these two subsets are truly distinct, whether there can be interchange between the pools, or whether there is a single pool of such molecules used for both purposes. A third portion is spliced to yield subgenomic mRNAs. For the simple retroviruses, there is a single spliced mRNA encoding the Env glycoprotein. For the complex viruses, there can be multiple alternatively spliced mRNAs, encoding both Env and an array of auxiliary proteins. Examples of the complicated array of mRNAs that are formed for both simple and complex viruses are shown in Figure 47.14. The protein products of these multiply spliced mRNAs will be discussed in Chapters 48–52.

The splicing and subsequent export from the nucleus of only a portion of an initially transcribed RNA is an extraordinary process; normally splicing of cellular mRNA precursors goes to completion, and only then is the mRNA exported. The export of a precursor mRNA is prevented until splicing is complete.

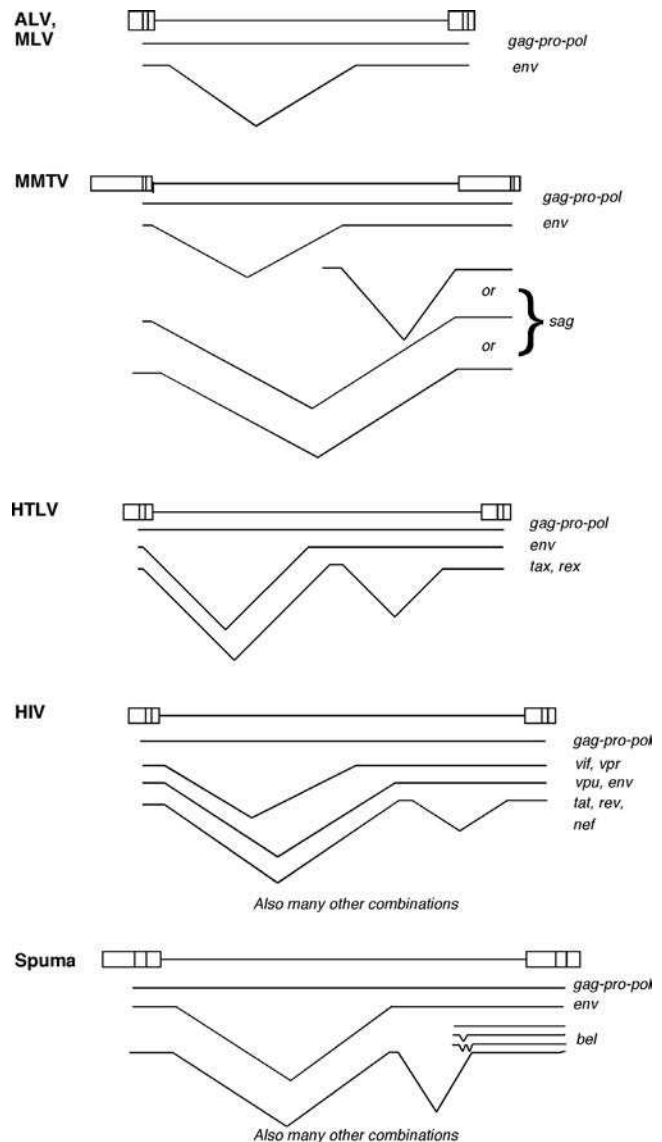

FIGURE 47.14. Splicing patterns of representative retroviral RNAs.

All retroviruses direct the synthesis of an unspliced RNA transcript, as well as a variable array of subgenomic mRNAs. Examples of the splicing patterns of the mRNAs of various retroviruses are shown. The complex viruses such as HIV-1 also encode a larger array of mRNAs containing various combinations of exons.

At least three aspects of the retroviral genome may promote the export of unspliced mRNAs. First, the splice sites of the viral RNA may have poor overall efficiency of utilization by the splicing machinery in the cell.²⁸⁰ The sequences at the splice donor and acceptor regions are often poor matches to the consensus sequences for splice sites, and mutations that make the sites better matches increase splicing and are actually deleterious to virus replication. These mutations can be suppressed by secondary mutations that reduce splicing efficiency. The overall folding of the RNA may affect the efficiency of splicing; thus, sequences at some distance, as in the *gag* gene, may modulate splicing.⁵⁶⁵

Second, studies of ASLV have identified specific sequences that act as negative regulators of splicing (NRS) through their

interaction with host factors.^{11,378,379} These elements can be important for the expression of transduced genes in some viruses.⁵⁵⁸ Similar signals may exist in other viruses; mutations in the Gag region of MuLV can affect RNA processing in complex ways.

In addition, unspliced mRNAs contain *cis*-acting elements that promote the export of the RNA out of the nucleus, the so-called constitutive transport elements (CTEs).⁶⁸ These sequences are located near the 3' end of the genomic RNA of MPMV, and possibly in similar regions of ASLV. The CTE is recognized by one or more host proteins that assemble a complex onto the RNA to mediate its export, including Tap and its cofactor Nxt. In the complex viruses, RNA export is regulated through complex interactions of the Rex or Rev gene products with *cis*-acting sites, the RRE elements that promote RNA export; and of various host factors with the CRS/INS elements that prevent it (see 121 for review). The key players include Crm1, a cellular nuclear export factor, and DDX3, an RNA helicase (see Chapter 49 for detailed discussion of the mechanism of Rev action).

Viral RNAs are subject to other modifications common to cellular mRNAs. Like cellular mRNAs, the N6 position on specific A residues can be methylated, and other sites can be modified by dsRNA adenosine deaminase. The significance of these modifications is uncertain.

TRANSLATION AND PROTEIN PROCESSING

All retroviral genomes, at a minimum, contain ORFs designated the *gag*, *pro*, *pol*, and *env* genes. These genes are expressed by complex mechanisms to form precursor proteins, which are then processed during and after virion assembly to form the mature, infectious virus particle. The expression of the various proteins as large precursors that are subsequently cleaved provides several advantages: it allows for many proteins to be made from one ORF; it ensures that the proteins are made at proper ratios; and it allows for many proteins to be targeted to the virion during assembly as a single entity. The *gag*, *pro*, and *pol* genes are expressed in a complex way from the full-length unspliced mRNA. The arrangement of these genes, and especially the way *pro* is expressed, are different in different viruses. A summary of the arrangement of the ORFs of various viruses is shown in Figure 47.15.

Gag Gene Expression

The *gag* gene is present at the 5' proximal position on all retroviral genomes. A full-length mRNA, identical in sequence to the genomic RNA, is translated in the cytoplasm to form a Gag precursor protein, in the 50 to 80 kDa range. Translation begins with an AUG initiator codon and proceeds to a terminator codon at the 3' end of the ORF. The viral RNA typically contains a relatively long 5' untranslated region, and there has been uncertainty regarding whether ribosomes could scan from the 5' cap to the start codon for Gag translation. These 5' RNA sequences are predicted to contain stable secondary structures that would inhibit scanning. Furthermore, the long 5' UTRs often contain AUG codons in contexts that are favorable for translation, that are not in frame with the *gag* ORF, and presumably would inhibit successful translation of Gag. Experiments suggest that for the MuLVs and related endog-

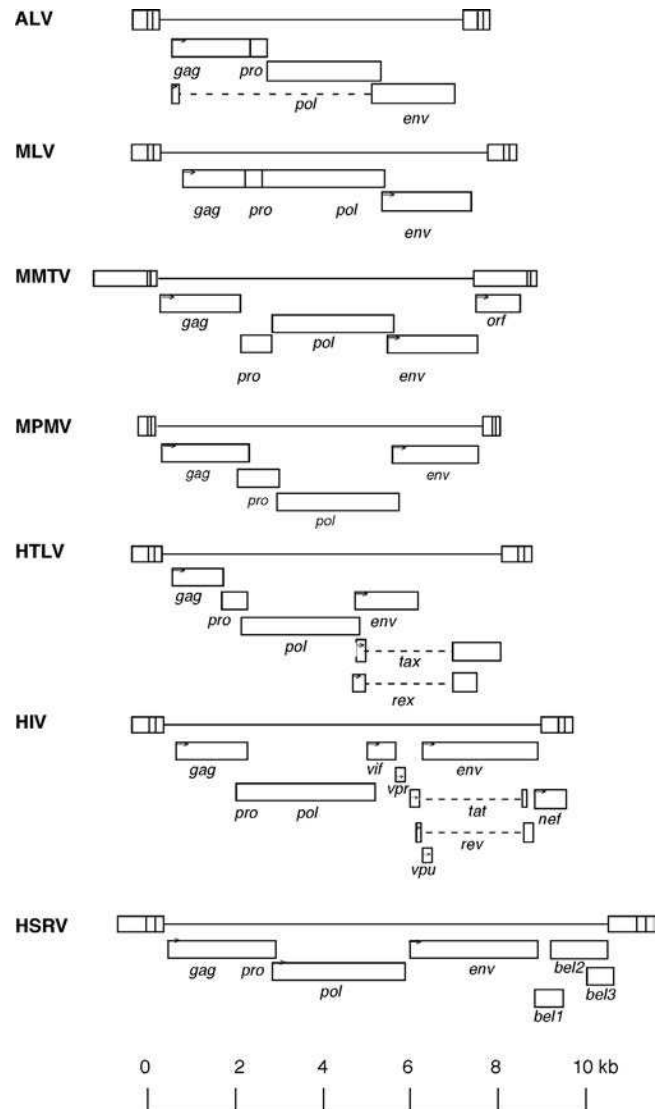

FIGURE 47.15. Arrangements of the open reading frames (ORFs) encoded by various retroviruses. The major ORFs of each virus are indicated by the open boxes. ORFs in the same reading frame are in the same line, and ORFs in different frames are on different lines. Translational starts are indicated by small arrows. Spliced introns are indicated by dashed lines.

enous RNAs, an internal ribosome entry site (IRES) is present near the start of the *gag* ORF and is used to initiate translation in a cap-independent mechanism.^{45,46,344} Thus, at least in these viruses, ribosomes can bind directly near the *gag* gene and do not need to scan the mRNA. Although the suggestion is not without controversy,³⁸³ it is likely that many other viruses, including HIV-1, also utilize IRES elements for translation of Gag.^{130,131,427} In the case of HIV-1, the IRES is remarkable in that critical sequences extend downstream of the AUG, lying within the Gag coding region.⁷⁶

Some retroviruses encode an additional Gag protein besides the major product, termed gPr80^{gag} or “glycoGag.” This Gag protein is longer than the major product and derives from translational initiation at a nonconventional CUG codon

upstream from the initiating AUG codon. Translation beginning at this codon first forms an N-terminal leader sequence and then proceeds in the same reading frame through the normal AUG and the rest of the Gag protein. Thus, where the proteins overlap their sequences are identical. The leader sequence contains a functional signal peptide directing the translation machinery to the endoplasmic reticulum, and specifying that the Gag protein be co-translationally inserted into the secretory pathway. The Gag become glycosylated at several sites, is transported via the golgi to the cell surface, and persists for some time as a membrane-bound glycoprotein, with the carboxyterminal domain exposed on the cell surface.⁴⁷⁶ The protein is processed into several fragments and has a relatively short half-life. It is not required for virus replication in some cells.⁵⁴² However, the protein can facilitate release of virus at lipid rafts,⁴²⁰ apparently acting in concert with the host La protein,⁴²¹ and can replace the function of the HIV-1 Nef protein in promoting virion release.⁴⁷⁹ Very recent work suggests that GlycoGag serves to inhibit the Apobec3 restriction factor.

The major Gag product is often modified by the addition of myristic acid, a relatively rare 14-carbon fatty acid, to the penultimate aminoterminal residue, a glycine.²³⁴ The addition is mediated by a myristyl CoA transferase that co-translationally transfers myristate from a myristyl CoA donor to the amino group of the glycine residue, forming an amide bond. The fatty acid is important for the membrane localization and binding of the Gag precursor, increasing the hydrophobicity of the aminoterminal domain. Mutant Gags in which the glycine is altered are not modified; these Gags do not associate with membrane properly and do not aggregate to form virions.^{75,210,500} It should be noted that although the myristate is important, it is not sufficient for membrane targeting; hydrophobic residues in the MA domain are also required. Furthermore, basic residues further downstream in the MA of some viruses form a patch of positive charge that interacts with negatively charged phospholipids in the membrane.

An aminoterminal myristate is not found on the Gags of BIV, EIAV, visna, or ASLV. For the avian retroviruses, the aminoterminal is not myristylated but rather acetylated. The Gag protein of these viruses is apparently sufficiently hydrophobic to be targeted to the membrane without the fatty acid in avian cells, though, curiously, not for ASLV in mammalian cells. Alteration of the avian Gag to allow its myristylation permits virion assembly in mammalian cells⁶³³ and does not block its function in avian cells.

pro Gene Expression

The relative position of the *pro* gene on retroviral genomes is always similar—in between *gag* and *pol*. However, the *pro* gene is expressed in very different ways in different viruses. Sometimes it is fused in frame onto the 3' end of *gag*, sometimes it is fused to the 5' end of *pol*, and sometimes it is present as a separate reading frame. These various patterns have led to considerable confusion in the literature; sometimes *pro* is considered a portion of *gag*, or sometimes of *pol*. Because of these different patterns of expression, it is best to consider this ORF as a separate gene.

The various arrangements of the *pro* gene and its mode of expression are as follows. For the alpharetroviruses, *gag* and *pro* are fused and expressed as a single protein; *pol* is in a different reading frame, and a frameshift is used to express the Gag-Pro-Pol polyprotein. For the betaretroviruses and deltaret-

roviruses, *gag*, *pro*, and *pol* are all in different frames and successive frameshifts are used to express Gag-Pro and Gag-Pro-Pol polyproteins. For the gammaretroviruses and epsilon-retroviruses, *gag* and a *pro-pol* fusion are in the same reading frame and separated by a stop codon, and translational readthrough is used to make Gag-Pro-Pol. For the lentiviruses, *gag* and a *pro-pol* fusion are in different reading frames, and frameshifting is used to make Gag-Pro-Pol. Finally, for the spumaviruses, *pro* is fused to *pol*, and the Pro-Pol protein is expressed without Gag, from a spliced mRNA. More about these varied mechanisms of expression is presented in the following section.

pol Gene Expression

The *pol* gene encodes several proteins needed at lower levels for the replication of the virus, including the reverse transcriptase and integrase enzymes. The *pol* ORF is not expressed as a separate protein in most retroviruses, but rather is expressed as a part of a larger Gag-Pro-Pol fusion protein. The Gag-Pro-Pol protein must be made at the correct abundance, in proportion to the amount of Gag protein, for efficient assembly of infectious virus; expression of only Gag-Pro-Pol does not result in virion assembly.^{170,458} The formation of this protein is mediated by one of two mechanisms, depending on the virus.

Translational Readthrough

In the gammaretroviruses and epsilon-retroviruses, the Gag and Pro-Pol ORFs are in the same reading frame, separated by a single UAG stop codon at the boundary between Gag and Pro-Pol. The translation of Gag-Pro-Pol in these viruses occurs by translational readthrough—that is, by suppression of termination—at the UAG stop codon.⁶⁵¹ Most of the time, translation of the RNA results simply in the formation of the Gag protein. But approximately 5% to 10% of the time, ribosomes translating the RNA do not terminate at the UAG codon, and instead utilize a normal aminoacyl tRNA, usually a glutamine tRNA, to insert an amino acid at the position of the stop codon. Translation then continues, in frame, through the entire long *pro-pol* ORF, resulting in the formation of a long Gag-Pro-Pol precursor protein.

The high-level suppression of termination is specified by a specific structure in the RNA immediately downstream of the UAG stop codon.^{241,449} The precise features of this structure that are required for suppression are not completely known, but they include a purine-rich sequence immediately downstream of the stop codon, and a pseudoknot formed from the next 60 or so nucleotides.¹⁷² The structure may slow translation, and it may also in some other way alter the balance between termination, which requires binding of termination factors eRF1 and eRF3 by the ribosome, versus incorporation of an amino acid, which requires misreading of the codon by an aminoacyl tRNA. No changes in the tRNA pool occur during infection. The signals in the RNA can operate to mediate suppression of both UAA and UGA termination codons as well as UAG.

A screen for proteins interacting with the MuLV RT resulted in the identification of the eukaryotic termination factor eRF1, and subsequent studies showed that overexpression of RT could inhibit termination and promote translational readthrough of the Gag stop codon *in vivo*.⁴³⁴ Mutant viruses with point mutations in RT blocking the interaction with eRF1 were unable to express normal levels of Gag-Pol and failed to replicate. These results suggest that RT, likely in the context of the nascent

Gag-Pol protein, can bind and inhibit eRF1, increasing the level of readthrough to increase its own synthesis. The final level of Gag-Pol produced in this positive feedback loop presumably is ultimately limited by other factors.

Translational Frameshifting

In the alpharetroviruses and lentiviruses, the *gag* and *pol* ORFs lie in different reading frames, and the formation of the Gag-Pro-Pol fusion is mediated by a translational frameshift mechanism.²⁵⁷ Most of the time, translation again results in the simple formation of the Gag protein. But approximately 10% of the time, as the translation approaches a specific site near the end of the *gag* ORF, the ribosome slips back one nucleotide (a -1 frameshift) and proceeds onward in the new reading frame. The ribosome passes through the stop codon out of frame and continues to synthesize protein using the codons of the *pol* ORF. As for readthrough, the determinants of frameshifting lie in the RNA sequence and structure near the site of the event. The requirements for frameshifting include a “slippery site,” a string of homopolymeric bases where the frameshift occurs; these are oligo U or oligo A in different viruses. In addition, the frameshifting requires either a very large and near-perfect hairpin or stem-loop structure (as for HIV-1 group M viruses); or a large pseudoknot structure (as for HIV-1 group O viruses), similar to those used in readthrough, though apparently containing a distinctive bend at the junction of the two paired sequences. As for readthrough, the proper frameshifting efficiency is crucial for normal virus replication.

In the betaretroviruses (e.g., MMTV) and deltaretroviruses (e.g., BLV, HTLV-1), the *pro* gene is present as a separate ORF, in a different reading frame from that of *gag* or *pol*. Two successive frameshifts are utilized to make the long Gag-Pro-Pol fusion protein. Near the 3′ end of the *gag* ORF, ribosomes carry out a first (-1) frameshift and continue into the *pro* ORF; near the 3′ end of the *pro* ORF, they perform a second (-1) frameshift and continue on into the *pol* ORF. These two frameshifts occur at extremely high frequencies—as much as 30% of the time that the ribosome transits through each site—so that the overall frequency of formation of the Gag-Pro-Pol protein is perhaps 10% that of formation of Gag.

Separate Pol Expression

The spumaviruses are unique among the retroviruses in that the synthesis of the Pol protein is not mediated by the formation of a Gag-Pol fusion protein. Instead, a subgenomic spliced mRNA is translated directly to form a separate Pro-Pol protein.^{159,340} This protein must be directed to the assembling virion by distinct domains rather than by the Gag portion of a Gag-Pol fusion.

env Gene Expression

In all retroviruses the *env* gene is expressed from a subgenomic mRNA. The *env* message is a singly spliced mRNA, in which a 5′ leader is joined to the coding region of *env*. Thus, the bulk of the *gag* and *pol* genes are removed as an intron from the mRNA. The resulting message is exported to the cytoplasm and translated from a conventional AUG initiator codon. In the alpharetroviruses, the AUG is actually the same one used for Gag translation; it lies in the leader, and the splicing brings this AUG and the first six codons into frame with the *env* coding region. The first translated amino acids constitute a hydro-

phobic signal peptide, and direct the nascent protein to the rough endoplasmic reticulum. The leader is removed by a cellular protease (the signal protease) in the ER, and the protein is heavily glycosylated by transfer of oligosaccharide from a dolichol carrier to asparagine residues on Env. These residues lie in the conventional Asn-X-Ser/Thr motifs recognized by the modification enzymes. Near the end of the co-translational insertion of Env into the ER, a highly hydrophobic sequence acts as a stop transfer signal to anchor the protein in the membrane. The remaining C-terminal portion of the protein stays on the cytoplasmic side of the membrane.

Before the Env proteins are transported to the cell surface, they are folded and oligomerized in the ER. The formation of oligomers is required for stable expression of the protein, and is sensitive to overall conformation; many mutants of Env show defects in oligomerization.⁵⁹⁹ Envelope proteins generally form trimers in the mature virus.³⁴⁷ The most studied envelope proteins (ASLV and HIV-1) may pass through dimeric or tetrameric intermediates, but the nature of these intermediates is not clear. The folding of the protein is presumably catalyzed by chaperone proteins in the ER and the formation of disulfide bonds between various pairs of cysteine residues by disulfide interchange enzymes.

The Env protein is then exported to the Golgi and cleaved by furin proteases to form the separate SU and TM subunits. This cleavage is essential for the normal function of the Env protein. The cleavage occurs at a dibasic pair of amino acids,¹³⁹ producing a hydrophobic N-terminus for the TM protein that is required to mediate fusion of the viral and host membranes during virus entry. In the Golgi the sugar residues are modified by the sequential removal of mannose residues and addition of N-acetyl glucosamine and other sugars to many of the oligosaccharide. O-linked glycosylation and sulfation of Env glycoproteins have also been documented.⁴⁷⁸ The pathway by which Env is transported to the cell surface is not fully understood, but presumably host vesicular transport systems are utilized. There is evidence that clathrin adaptor complexes interact with the cytoplasmic tail of Env and direct its movement to the plasma membrane. The protein typically becomes a prominent cell-surface protein on the infected cell.

In polarized epithelial cells, Env proteins are often restricted to the basolateral surface of the cell.⁴⁴¹ This localization is mediated by a tyrosine-based motif, Yxxf, present in the cytoplasmic tail of Env⁴⁴² (x, any amino acid; f, hydrophobic residue). Remarkably, this targeting of Env can redirect the budding of Gag proteins to this surface.

Other Viral Gene Products

The complex retroviruses express a number of small proteins with a range of functions. The proteins are translated from subgenomic mRNAs, usually resulting from multiple splicing events that join a 5′ LTR to a number of small exons encoding the protein. These gene products will be discussed in greater detail in Chapters 48–52 (see 120,215,482 for reviews).

Betaretroviruses

- *Sag*: The MMTV genome encodes a small protein whose function seems to be to act as an antigen to stimulate lymphocyte activation, providing a suitable tissue for virus replication.⁴⁹²
- Rev-like protein: MMTV encodes a protein involved in RNA metabolism.²⁵³

Deltaretroviruses

- *Tax*: The Tax gene product is a positive regulator of transcription from the viral LTR. Tax functions in association with the activating transcription factor/CRE-binding protein (ATF/CREB) by binding to three cAMP response elements in the viral LTR. Tax also plays a role in transformation, perhaps through Rb destruction, E2F-1 activation, or through effects on the cell cycle.²⁸⁷
- *Rex*: The Rex gene product facilitates the export of unspliced and singly spliced viral mRNAs from the nucleus. Its action is probably similar to that of the lentiviral Rev protein.

Epsilonretroviruses

- *Orf A*: The Orf A product of the piscine retroviruses is a cyclin D homolog that functions as a cyclin in yeast.³¹⁴ The function of the protein in virus replication or tumor formation is uncertain.
- *Orfs B, C*: The function of these Orfs is unknown.

Lentiviruses

- *Tat*: The Tat protein is a potent transactivator of transcription from the viral LTR. The protein acts by binding to a hairpin structure, the TAR element, encoded in the R region of nascent viral RNA, and recruiting host factors cyclinT and Cdk9 to the RNA. Tat does not increase the rate of RNA polymerase II initiation, but seems to enhance its processivity or elongation, perhaps by phosphorylation of the CTD of Pol II.
- *Rev*: The Rev protein mediates the export of the unspliced and singly spliced viral RNAs from the nucleus, thus permitting the expression of the Gag, Pol, and Env gene products. Viral RNAs contain multiple sequences, called CRS or INS elements, which bind several proteins—PTB/hnRNP I, hnRNP A1, PABP1, and p54nrb/PSF—that retain the RNAs in the nucleus.^{5,674} Rev binds to the Rev-responsive element (RRE) present in the HIV-1 *env* gene and by interacting with the importin Crm1 acts to export the viral RNAs through the nuclear pore, overriding the retention signals.
- *Nef*: The Nef protein is a multifunctional protein not essential for replication in some cells in culture, but important for replication *in vivo*. Nef-defective viruses do not induce high-level viremia in infected animals, and progression to disease is delayed or prevented. Nef downregulates the CD4 receptor from the cell surface,¹⁹⁷ facilitating virus release, probably by bridging CD4 to adapter proteins (APs).⁴⁷⁵ Nef also downregulates MHC class I levels, thereby inhibiting the CTL-mediated lysis of HIV-1-infected cells. The Nef of SIV can promote virion assembly and release by antagonizing the antiviral protein tetherin.⁶⁶⁴
- *Vpr*: The Vpr protein, as noted below, is packaged at high levels into virion particles through an interaction with the p6 domain of Gag.^{23,263,545} Vpr may facilitate the import of the preintegration complex into the nucleus in nondividing cells. Vpr also causes a strong cell-cycle arrest in the G2 stage of the cell cycle, perhaps through an indirect inhibition of Cdc25 phosphatase activity. Vpr binds via VprBP/DCAF1 to a ubiquitin ligase complex containing Cullin 4A and DDB1, presumably to promote the ubiquitinylation and degradation of unknown targets, perhaps including the cell-cycle regulator Ctd1.^{244,536}

- *Vif*: The Vif protein is expressed at high levels in the cytoplasm, and is packaged into virion particles of both homologous and heterologous viruses. Vif enhances infectivity by degrading or sequestering the APOBECs, a family of cytidine deaminases that attack the msDNA during reverse transcription.^{54,224}
- *Vpu*: The Vpu gene product, found only in HIV-1, is a membrane protein that enhances virion production by antagonizing tetherin, which traps virions on the cell surface and prevents their spread to neighboring cells.⁴¹⁴ Vpu also mediates the degradation of CD4 by the ubiquitin-conjugating pathway.⁵³⁸
- *Vpx*: Some SIVs encode a small protein, Vpx, which enhances early steps of infection and overcomes a block to infection of monocyte-derived macrophages and dendritic cells. Vpx acts by targeting the antiviral protein SAMHD1, a nuclease, for degradation.^{245,311}

Spumaviruses

- *Tas*: The Tas (or Bel1) protein is a transactivator of transcription from the viral LTR, acting at sequences near the 5' end of the genome. Its mechanism of action may be similar to that of the lentiviral Tat protein.
- *Bet, Bel2, and Bel3*: The functions of the *bet* (and overlapping *bel2*) and *bel3* genes are uncertain. Bet, like HIV-1 Vif, inhibits APOBEC3G,^{341,524} and the Bel3 protein may be a negative regulator of replication.

VIRION ASSEMBLY

As the Gag, Gag-Pro-Pol, and Env proteins are synthesized, they come together to form progeny virions (for reviews, see 251,528,579,632). The assembly of the retrovirus particle is driven primarily by the Gag precursor protein. Gag is required for the formation of a virion, and is sufficient to mediate the assembly and release of an immature “bald” particle—lacking infectivity and the “hair” of the Env protein. The Gag protein that is responsible for assembly is the uncleaved Gag precursor. This form of the protein is thus targeted for assembly and export—the “way out” of the cell. The trafficking routes that deliver Gag to the site of assembly and budding are not established with certainty for any retrovirus. Once the Gag proteins are processed by the viral protease, changes in virion structure occur to promote virus entry—the “way in” to the next cell.

There are two major routes by which the various retroviruses assemble their virions, discussed in the next section.

Assembly of C-Type Virions

For most of the retroviruses, those with C-type morphology, assembly occurs at the plasma membrane. In these cases the Gag precursor protein is targeted to the cytoplasmic face of the plasma membrane by hydrophobic sequences, basic residues, and sometimes by a myristic acid moiety,²³⁴ present at the aminoterminal. It is not clear if monomeric, dimeric, or higher-order structures of Gag are transported to the membrane to begin assembly. The Gag proteins aggregate, presumably by side-to-side contacts, and create a patch under the membrane. As the patch of protein grows, curvature is induced in the membrane, causing the nascent virus to bud outward. The bud eventually grows to a complete sphere, attached to the

FIGURE 47.16. Schematic diagram of the process of virion assembly. The Gag precursor, containing the MA, CA, and NC domains, and the Gag-Pol precursor, containing the MA, CA, NC, PR, RT, and IN domains (see *magnification*), are transported to the inner leaflet of the plasma membrane. The proteins bind the viral genomic RNA (*thin line*). Curvature is induced in the membrane as the virion grows, and the roughly spherical particle is finally pinched off and released from the cell. The virion proteins are reorganized upon processing by the viral protease to form the mature, infectious virus (*top*).

cell by a narrow stalk. The stalk is then pinched off, the virion is released, and the host membrane is sealed. The structure of the immature virion is roughly spherical, with Gag arranged radially.⁶²⁹ The various steps are depicted in Figure 47.16.

The route of transport of Gag from the cytoplasm to the cell membrane may not be simple or direct. A substantial amount of Gag protein is found in the nucleus,^{411,533} and the Gag in this compartment may be a precursor to the molecules on the plasma membrane.⁴⁵⁵ Whether this is an obligatory step in virion assembly is unclear, but genomic RNA for packaging may be bound in the nucleus.¹⁹⁶ There is also evidence that Gags, perhaps bound to the genomic RNAs that they will package into particles, are trafficked to the plasma membrane on endosomal vesicles.³¹

Assembly of B- and D-Type Virions

In the alternative lifestyle exhibited by viruses with B- and D-type morphology, the betaretroviruses and the spumaviruses assemble in the cytoplasm, then are subsequently transported to the plasma membrane for envelopment and release.⁵⁰⁷ These two pathways would seem relatively distinct, and one might have supposed that the two groups of viruses would have evolved very different requirements for assembly, and that the details of the Gag-Gag interactions would be different. But these two mechanisms are not so far apart. A single amino

acid substitution in the MA protein of M-PMV can change the morphogenetic pathway of the virus from a cytoplasmic site of assembly to a membrane site of assembly.⁵⁰⁹ Thus, the main difference may be the timing of exposure of determinants for membrane transport: in the C-types, such a determinant might be constitutively available, while for the B- and D-types, the determinant may not be exposed until assembly occurs. For both mechanisms, the nascent virions consist of a spherical particle surrounded by a lipid bilayer that is pinched off from the cell and then released into the extracellular space.

MPMV Gag does not seem to assemble at the site of translation; the protein apparently first travels in a microtubule-dependent process to the pericentriolar region of the cytoplasm through interactions between a short peptide signal, known as the cytoplasmic targeting-retention signal, and the dynein/dynactin motor. The Gag precursors are assembled to form immature capsids in pericentriolar microdomains. Env may affect release of Gag from the centriolar region. Mutants of Rab11 that inhibit efflux of transferrin from the recycling endosome and Env localization also inhibited Gag transport.^{546,547} The mechanism of the subsequent movement to the cell surface is uncertain.

Gag and Virion Assembly

For most retroviruses, the expression of the Gag precursor is sufficient to mediate virion assembly and release, earning the

protein the name of the “particle-making machine.” (An exception to this rule is the foamy viruses, which also require the presence of the Env glycoprotein for efficient budding.) Because of their central role in virion assembly, the Gag proteins have been subjected to intense mutational analyses to define the domains required for various steps in the process.^{223,632} Surprisingly small portions of Gag, containing only a few critical regions, can still assemble virions.⁶¹⁸ Three domains, at least, seem to be crucial: a membrane-binding (M) domain; an interaction (I) domain; and a late-assembly (L) domain. It is important to remember that the form of the Gag protein that is mediating assembly is the precursor; thus, the assembly domains need not lie nearly within any of the cleavage products that form later and can span cleavage sites.

The M Domain

The M domain, or membrane-binding domain, ranging from 30 to 90 residues in length, is located in MA at the amino terminus of Gag. Mutations affecting this domain abolish assembly, but M mutants retain their ability to interact with other Gags and can be rescued into particles by the co-expression of a wild-type protein. The region seems to contain both hydrophobic and basic residues that are needed for proper interaction with lipid and with the acidic moieties of phospholipids. Structural information for the isolated M domain is consistent with this role. How Gag finds specific membranes is unclear, but M domains seem to be involved.⁵³⁴ There is evidence that budding is enhanced at membrane regions of unusual lipid composition termed lipid “rafts”,^{84,410,417,418,431} defined by high levels of phosphatidylinositol (4,5) bisphosphate.⁴²⁹

For many retroviruses, myristoylation of Gag, along with specific residues in MA, is required for membrane binding. This interaction with membrane, in turn, is important for virion assembly of the C-type viruses and for their proper subsequent Gag processing.⁵³⁹ Mutational studies have led to the notion of a “myristyl switch,” in which the myristic acid is exposed to mediate plasma membrane binding during virion assembly, but then can be sequestered in the compact globular core of MA after Gag processing.^{430,444,561,670} Although this region is generally considered important for virion assembly, surprisingly, much of the RSV MA and the entire HIV-1 MA domain can be deleted from Gag without preventing assembly, as long as a functional membrane-binding signal is retained. In the latter case, there are some effects on assembly: virions are budded indiscriminately into both intracellular membranes as well as at the cell surface. The aminoterminal sequences of Gag can be replaced with a heterologous membrane binding signal, such as that present at the aminoterminal of the Src kinase. It should be noted that the interaction of Gag with membrane is not required for assembly of the B- or D-type viruses *per se*. For these viruses, mutations in the myristate addition signals do not affect the cytoplasmic assembly of the virions, but rather block the transport of the assembled particles to the plasma membrane.⁵⁰⁸

The I Domain

The I (or interaction) domain is defined as a major region of Gag–Gag interaction, largely contained in the NC region. Although the major I domain has been suggested to lie in NC, some analyses have suggested that the C-terminal half of CA and NC are equally important for normal assembly. Mutations in the I domain block or reduce assembly,⁴⁰² and those particles

produced by these mutants have aberrantly low density, indicating fewer and poorly packed Gag proteins. The key feature of the I domains is not the zinc-binding residues of the cys-his box, but rather basic residues flanking the boxes that interact with nucleic acid. RNA bridging between NCs is likely a critical step in virion assembly. The assembly functions of NC can be replaced by foreign proteins, and the key activity seems to be the formation of protein–protein contacts.^{266,669} Mutations in this region can affect particle size as well as yield.

The L Domain

The third assembly domain is the L (or late) domain.^{631,645} Mutants affected in this function fail to produce and release particles efficiently, and though the mutant Gag proteins form spherical structures, they accumulate under the membrane and do not progress normally. The buds remain tethered to the cell surface by a membrane stalk, suggesting that the function of the L domain is to mediate virus–cell separation. L domains lie at different locations in the Gag proteins of different viruses. In ASLV, MPMV, and the MuLVs, the L domain lies in the amino terminal third of the protein, and its critical residues are PPPY. In HIV-1, the domain lies in p6, at the C-terminus, and instead contains the motif PTAP. In EIAV, the domain lies in p9, and contains the motif YPDL. Many viruses contain more than one L domain, and in such cases each domain can provide partial function. Remarkably, many (though not all) of these L domain motifs are interchangeable among the various retroviruses, and show a substantial position independence for their function.^{327,437,456,658} L domains have been shown to be important for the release of many budding viruses, including VSV, rabies virus, and Ebola.

The L domains are now appreciated as serving as the binding sites for various components of a host machinery normally involved in protein sorting and delivery into late endosomal compartments, the multivesicular bodies.^{198,394,407,572,588} The complex that carries out these trafficking events contains more than 20 distinct proteins held together through a network of protein–protein interactions.⁶¹⁴ Most show strong similarity to the so-called VPS proteins of the yeast ESCRT (endosomal sorting complexes required for transport) complexes, identified genetically as involved in vacuolar protein sorting in yeast.^{21,22} The proteins have been divided into three groups: the ESCRT-I complex, containing Vps28, Vps37C,¹⁵⁰ and *Tsg101*, a gene first identified as a tumor suppressor locus³²⁸; ESCRT-II, containing Alix/AIP-1 and several other proteins; and ESCRT-III, containing Vps4A and a large number of CHMPs (for Charged MVB proteins). The PTAP/PSAP class of L domains is bound by Tsg101; the PPPY class of L domains is recognized by various members of the Nedd4 family, a group of ubiquitin ligases that interact with Tsg101; and the YPxL class is bound by Alix/AIP-1. Other proteins associated with the ESCRT complexes, including the vesicle-associated endophilins, may also bind Gag and play a role in virus budding.⁶¹⁹ Depletion of many of the ESCRT homologs, or overexpression of dominant-acting negative fragments of these proteins, can potentially inhibit retroviral budding and release.^{198,267} The biochemical steps of virion release that are actually promoted by the complex are not clear, but may involve membrane targeting, membrane bending, or lipid destabilization and reorganization. The process may involve the covalent transfer of ubiquitin to Gag—Nedd4 can act as a ubiquitin ligase, Tsg101 is a catalytically inactive version of a ubiquitin ligase,

and Gag is indeed ubiquitinated at low levels^{436,463,569}—but it remains controversial at this point as to whether the transfer itself is actually required.^{211,371,613} There is hope that the process of virion budding could be interrupted by a new class of antiviral drugs that target the Gag–ESCRT interactions.

Virion Assembly *In Vitro*

Gag proteins and fragments of Gag have been shown competent to assemble *in vitro* to form various structures that more or less closely resemble virion cores.^{155,296,529} The CA–NC portions of ASLV and HIV-1 expressed as recombinant proteins can assemble to form particles or long, hollow tubes. The formation of these structures is dramatically enhanced by addition of RNA or oligonucleotides,^{355,356} and in some settings the length of the tubes can be determined by the length of the RNA.⁸³ The arrangement of Gag proteins is clearly hexameric, with critical contacts between N- and C-terminal domains of CA.³³⁰ The aminoterminal residue of CA, a proline, is critical for proper folding and assembly.⁵²³

Larger Gag fragments that include more aminoterminal regions can assemble into spherical particles^{218,272}; this assembly is stimulated by RNA^{174,355,356} and host cell extracts.⁸² A critical component in these extracts, curiously, has been identified as inositol hexaphosphate,⁸¹ which interacts with MA. HIV-1 Gag CA–NC fragments can assemble into conical structures,¹⁹¹ with a pitch that falls into discrete values. Image reconstruction of these cones has allowed the formation of a model for the packing of the protein into hexagonal arrays.³³⁰ Virus-like particles have also been formed with the Gag proteins of MPMV in cell-free protein synthesis systems, and in bacteria.⁴¹⁵

Virion Size

The number of Gag proteins per virion particle is estimated to be in the range of 1,200 to 1,800, though this number may vary somewhat from virus to virus (and has been disputed).⁶⁹ The number of Gag–Pol proteins is roughly 10 to 20 times lower, approximately 100 to 200 per virion. It is unlikely that these proteins in the immature virus form a completely homogeneous, ordered crystalline array, but rather they may form a “protein micelle” that is somewhat fluid, like a lipid micelle. The diameter of even wild-type virus preparations is not tightly homogeneous but shows a distribution that suggests some flexibility in the structures during assembly. However, the average size of the particle is determined by the Gag protein, and mutants with alterations in Gag often show abnormal or excessively heterogeneous diameters.³⁰⁵ Mutations in the CA domain commonly show this phenotype. Thus, CA–CA contacts may play a role in determining the angle between Gags during their packing into a spherical shape.

Gag proteins of one virus are sometimes able to interact with the Gags of another virus to co-assemble and form mixed virion particles. Various mutants with alterations in the Gag proteins of the MuLVs can co-assemble into particles that show phenotypes of both parental Gags.^{277,499} Viruses of very different genera can even form mixed particles in some cases.

Incorporation of Other Proteins into Assembling Virions

During assembly, other proteins are incorporated into the particle by contacts to Gag; these include Gag–Pol, Env, and auxiliary proteins encoded by the complex viruses. The Gag–Pol

precursor is thought to be incorporated into the assembling bud by virtue of the Gag protein present at the aminoterminal. Gag to Gag–Pol contacts can in some cases lead to the incorporation of mutants of Gag–Pol that do not retain the myristate modification to the aminoterminal,⁴⁵⁹ suggesting that the interaction is very strong. Gag fusions to foreign proteins can be similarly incorporated into particles formed by Gag²⁷¹; this process can even be used to target antiviral proteins into virions. Consistent with this notion, many mutations that block assembly of Gag, when tested in the context of Gag–Pol, are found to have similar effects on the incorporation of Gag–Pol.^{119,543} However, some mutations in HIV-1 Gag have also been identified that specifically affect the incorporation of Gag–Pol, suggesting that Gag–Pol utilizes some distinctive contacts not important for Gag–Gag interactions.⁵⁵⁴ Further, in the spumaviruses, Pol is incorporated without an appended Gag region, suggesting that distinct interactions must be utilized for its incorporation.¹⁵⁹

The Env protein is thought to be concentrated at the sites of budding and incorporated into the virions by virtue of contacts between the cytoplasmic tail of Env and the aminoterminal portion of Gag. These interactions have been difficult to document directly, though there is some biochemical^{113,644} and cross-linking studies in support of these contacts. Genetics has provided good evidence for this interaction. Selected mutants of MA show defects in Env incorporation,^{141,181} and some mutants of the cytoplasmic tail of TM are not efficiently incorporated.^{400,401,657} In addition, Env proteins that are specifically directed to the basolateral surface of polarized epithelial cells can redirect the sites of budding of Gag from a nonspecific assembly on both membranes to the exclusive assembly at basolateral membranes, and can similarly redirect Gag in neurons. Finally, mutants and revertants of these mutants with second-site suppressors in the binding partner have provided strong evidence for these interactions.^{181,182} However, it should be noted that the envelope proteins of viruses very distant from retroviruses, including VSV and influenza, can be functionally incorporated into retrovirus particles without any obvious sequence similarity in their cytoplasmic tails. Furthermore, truncating the tail of ASLV Env does not prevent its incorporation or function.⁴⁶⁶ Thus, there may be mechanisms to direct Env proteins to assembling virions without these specific contacts to Gag—a default pathway, or a pathway using other interactions. Other distinct parts of Gag, including the p6 region of HIV-1 Gag, have been implicated in Env incorporation.

The HIV-1 protein Vpr is efficiently incorporated into assembling virions at very high levels, approaching equimolarity with Gag. This incorporation requires the presence of the p6 domain of Gag⁵⁴⁵ and may be mediated by a direct interaction.²³ The binding can be used to direct foreign proteins into the particle; a fusion between Vpr and a foreign protein will be targeted to virions. Furthermore, Vpr can be used to direct separately expressed versions of RT or IN to particles in a functional form, to complement mutations in the RT or IN domains of the Gag–Pol fusion.

Host Proteins in the Virion

A number of host proteins have been shown to be present inside the virion particle; in most cases the significance of the protein is unknown. Prominent among the virion-associated factors are a number of cytoskeletal proteins. These include

actin^{19,439,628} and various members of the ezrin-radixin-moesin (ERM) family, specifically including ezrin, moesin, and cofilin.^{438,439} Gag and especially the nucleocapsid protein of HIV-1 have been shown to directly bind to actin,^{506,628} perhaps offering a mechanism for its incorporation into the particle. A complication in analyzing virion-associated proteins is that virion preparations tend to be contaminated with substantial amounts of microvesicles, entities released by cells that exhibit a density and size very similar to that of virions, and containing an array of host proteins.⁴⁹

The virions of HIV-1 contain substantial levels of cyclophilin A, a protein proline isomerase of uncertain function but implicated in protein folding and signal transduction.^{179,348,593} The role of the virion-associated form is uncertain. Several other proteins have also been found in virions: a translational elongation factor, eIF-1a,¹⁰⁰ and a protein known as H03,³¹² with similarity to histidyl tRNA synthetase, are additional examples. An intriguing protein present in HIV-1 virions is lysyl tRNA synthetase (LysRS), the cognate synthetase responsible for the charging of tRNA (Lys), the primer tRNA for HIV-1.^{88,90,261} The incorporation of lysyl tRNA synthetase is mediated by a direct interaction with Gag, specifically the C-terminal portion of CA, and does not require the tRNA itself. The synthetase may facilitate tRNA incorporation.⁸⁸

Host proteins may also be attracted into virion cores by mechanisms other than Gag. The host uracil DNA glycosidase, responsible for removing uracil bases from DNA, was shown to be incorporated into virions by contacts to IN.⁶³⁰ The Ini1/Snf5 protein is also incorporated into virions through binding to IN.⁶⁶⁰ Another protein, the RNA transporter stau6n, is incorporated into virions, perhaps through contact with viral RNA.³⁹⁷

There are also substantial levels of host membrane proteins in the virion envelope. The mechanism of incorporation of these proteins into the virion is not clear, and in most cases again the significance is uncertain. However, one such molecule, MHC class I, is present at levels approaching those of the Env protein, and can be functionally significant in that xenogeneic antibodies targeted to MHC can neutralize the infectivity of viruses such as HIV-1.¹⁹

RNA PACKAGING

The RNA genome is incorporated into virions by virtue of interactions between specific RNA sequences near the 5' end of the genome, termed the packaging or Psi sequences, and specific residues in the NC domain of Gag (see 43,147). Direct binding is readily observed *in vitro* (e.g., see 44,146). Both partners in this interaction have been intensively studied.

Gag Sequences Important for Packaging

The Gag precursor is the form of the protein that is responsible for packaging viral RNA⁴²⁵; the NC portion of the precursor plays the largest role. Mutations affecting the NC protein often reduce the incorporation of the genomic RNA into the virion particle (see 43 for review). The most crucial sequences are the Cys-His boxes, short-sequence blocks resembling zinc fingers and containing the motif Cys-X2-Cys-X4-His-X4-Cys²⁰⁹; but basic residues elsewhere in the NC molecule are also important. Structures of the HIV-1 NC bound to various RNAs have

been resolved by NMR, revealing specific contacts between both hydrophobic and basic residues of NC and nucleotides in the stem-loop of the RNA.^{10,129} The NC protein of various viruses contains one or two copies of the Cys-His box. When two copies are present, they are not equivalent or interchangeable, suggesting that they mediate distinct interactions with RNA.²⁰⁷ Some viral cores can cross-package heterologous viral RNAs, suggesting good binding to the heterologous Psi region, and sometimes there is a strong preference for the homologous RNA. Exchanging the NC domains between viruses can sometimes transfer the preferential selectivity of a Gag protein for its cognate RNA, though the specificity of these hybrid Gags is often poor, and in some cases other sequences in Gag can determine the preference for RNA packaging by chimeric Gags.

Although Gags can obviously package RNAs in *trans*—that is, RNAs such as vector genomes that do not encode Gag—there may be enhanced encapsidation of the RNAs that encode Gag in *cis*, perhaps by the interaction of nascent Gag with RNA during its translation.^{216,283,331,483}

RNA Sequences Important for Packaging

The packaging or Psi regions on the viral RNA genome that are recognized for incorporation are distinct in nucleic acid sequence among the various viruses (e.g., see 406). The key Psi regions lie near the 5' end of the RNA, generally between the LTR and Gag.^{284,368,373,663} However, other regions of the genome can affect RNA packaging, including sequences upstream in R and in U5, downstream in Gag coding regions, and even near the 3' end of the genome. In the case of ASLV, a region of 270 nt is necessary and sufficient to mediate the packaging of a foreign RNA.²⁸¹ In the case of the MuLVs, sequences that are at least partially sufficient to mediate selective packaging have been similarly identified.^{1,36} These Psi regions are relatively autonomous; Psi can be moved to ectopic positions in the genome with at least some retention of function.³⁶⁷

Considerable effort has been focused on the structures of the 5' RNA of various viruses (e.g., 28,101–103,317,443,654, 663). The various Psi sequences have been predicted or shown to form a number of stem-loops, often containing GACG in the loops.^{129,145,317} Reversion analysis of mutants with alterations in these loops confirms the importance of the stem-loop structure. Mutational studies show that several such loops may incrementally contribute to the efficiency of packaging of the RNA, though one or two are often found to be most important.^{173,396} One of the stem-loop structures of the HIV-1 Psi was replaced by a completely foreign sequence that was selected on the basis of its binding activity with NC; the resulting RNA was efficiently packaged and utilized for replication, strongly suggesting that the binding to Gag is the key function of Psi.¹⁰²

Many cells contain vast arrays of endogenous proviruses and retrovirus-like elements, a subset of which can be expressed constitutively or under various conditions of stress to produce large amounts of genomic RNA. If such a cell is infected by an exogenous virus or has been engineered by expression constructs to produce virions, the particles will incorporate the endogenous RNAs along with the viral RNA.^{47,460} The endogenous retroviral RNAs, notably the VL30 RNAs of rodents, contain highly efficient Psi sequences,^{381,595} presumably because they were selected to compete with the homologous genomes of exogenous viruses for packaging.

Virions also contain a number of host RNAs of uncertain significance. There are substantial levels of 7S RNA, a low-molecular-weight RNA thought to function in host RNA splicing.²⁸⁶ In addition, there are low levels of host mRNA. Particles released without efficient packaging of the viral genome (as are produced by Psi-mutant genomes) may carry enhanced levels of host RNAs; various mutants with alterations in NC can show selective enhancement of both endogenous viral and host RNAs,³⁸¹ including ribosomal RNA and even intact ribosomes.⁴⁰⁴ A variant avian leukosis virus, SE21Q1b, packages unusually high levels of host RNA,^{187,337} and is capable of transducing these host sequences into new cells by reverse transcription.³⁵⁰ This phenotype of high-efficiency transduction is associated with an unusually high level of proviral expression and particle production rather than any specific alteration in a viral protein.¹²

Dimerization of the Viral Genome

Mature virions contain a dimeric RNA that is highly condensed into a stable, compactly folded structure referred to as the 70S dimer on the basis of its sedimentation rate. Specific sequences in the 5' end of the RNA,²³⁸ termed dimerization or dimer linkage sequences (DLS), are required for RNA dimerization *in vitro*, and for the formation of the dimeric virion RNA *in vivo*.^{42,353,398} These DLS structures are in close proximity or even intermingled with sequences required for packaging of the RNA, often making it difficult to determine their separate contributions to these processes.⁵³⁰ A model for the process of dimerization, the “kissing-loop” model, suggests that duplex formation between two RNAs is initiated between loops on the two RNAs and propagates outward through the stems through the action of NC.^{103,137,221,352,391,403,445,446,513,584}

Viral and even virus-host chimeric RNAs are normally always packaged as a dimer.²³⁷ Recent structural studies suggest that a high-affinity binding site for NC is sequestered by base pairing in the monomeric RNA, and that dimerization of the RNA exposes this and other binding sites, allowing tight binding by NC.^{134,148} This strongly suggests that dimerization might be a prerequisite for packaging. Further studies support this idea, and suggest that many mutations in the virus affect packaging by altering the monomer-dimer equilibrium and thus the amount of dimer available for NC binding.⁴³³ However, some ASLV mutants can apparently package monomeric RNA.^{435,457} Even here it remains possible that dimers are packaged but dissociate later.

The viral RNA in newly budded virions is present as a relatively unstable dimer, dissociated by heat at relatively low temperatures, and becomes condensed to a more stable dimer during virion maturation.^{185,481} This condensation requires the proteolytic processing of Gag¹⁸³ and may be mediated by the free NC upon its release from the precursor. It is likely that the paired regions of an unstable dimer are extended by NC.^{153,513,636} Dimerization may sometimes, but not always, require mature Pol proteins; RT and IN seem to be required for stable dimerization of HIV-1 RNA, but not MuLV or MPMV.^{80,550} The dimerization of viral RNAs can be induced *in vitro*, and is stimulated by addition of NC or the Gag precursor. However, it is uncertain to what extent these reactions reflect dimerization *in vivo*.

Incorporation of tRNA Primer

A key aspect of RNA packaging is the incorporation of a host tRNA along with the genome to serve as the initiating primer

for msDNA synthesis (for review, see 360). Virions contain a substantial pool of free tRNA, perhaps 50 to 100 copies per particle. The bulk of these tRNAs is not associated with the genomic RNA, and is present in virions that lack the genome. In some viruses these tRNAs are largely representative of the pool of tRNAs in the cell, while in others they are highly enriched for the tRNAs needed for priming DNA synthesis, though even here many other tRNAs are present. Viruses prepared without the Pol proteins do not show this enrichment, suggesting that Pol, and most probably the RT protein, are responsible for bringing these tRNAs into the virion.^{290,472} In accord with this notion, the RT of ASLV has been shown to preferentially bind tRNA trp from a mixture of tRNAs, accounting for its enrichment in the virion.⁴⁴⁸ Similarly, HIV-1 RT preferentially binds tRNA^{lys}3, and the interaction domain has been shown to at least include the anticodon loop of the tRNA. The incorporation of tRNA^{lys}3, and its placement onto the HIV-1 genome, are likely also catalyzed by the co-packaged lysyl tRNA synthetase.^{88,295} However, no similar preference for the natural primer tRNA^{pro} has been detected for the MuLV RT, nor is a tRNA synthetase apparently co-packaged in MuLV particles.⁸⁷ It may be significant that the MuLVs have been shown to be able to utilize a range of different primer tRNAs when only the complementary sequence in the genome (the pbs) is altered to promote their use.

tRNA Primer Placement

A very small subset of these tRNAs—two per virion—are annealed to the pbs, an 18-nt sequence near the 5' end of the genome with perfect complementarity to the 3' sequences of a specific primer tRNA. The pbs sequences are, as one would expect, essential for normal reverse transcription of the virus.⁵¹⁰ The sequence of the pbs can determine the primer tRNA that is utilized,⁶⁵⁵ but changes in the pbs tend to revert back to the wild type,⁶²⁷ suggesting that alternate tRNAs do not function well. An interesting aspect of reverse transcription provides for an efficient mechanism for this reversion: the use of the original tRNA even once during replication will convert the pbs back to the original sequence, because the tRNA itself is the template for the DNA copy of the pbs. Other sequence blocks of the tRNA are also paired with complementary sequences in R and U5 to form a large, complex structure required for proper tRNA primer placement and utilization.^{6,105,250,254,395} These other sequences are presumably responsible for the selectivity for the natural tRNA primer. In the alpharetroviruses, *pol* gene products are required to mediate the placement of the tRNA on the genome; but in the gammaretroviruses, *pol* is not required.¹⁸⁴ In the case of HIV-1, Gag and Pol proteins and the co-packaged lysyl tRNA synthetase are all required.^{86,89,250,290,332,519} The Gag precursor, especially the NC domain, are thought to play a major role in promoting the annealing of the tRNA to the genome. While NC can promote annealing of complementary RNAs and DNAs *in vitro*, its role and the mechanism by which it may act *in vivo* remain uncertain.

PROTEIN PROCESSING AND VIRION MATURATION

As retrovirions are budded from the cell surface, the Gag and Gag-Pro-Pol precursor proteins are proteolytically cleaved to

release the smaller proteins present in the infectious virions (for review, see 612). The cleavage of Gag and Gag-Pro-Pol is mediated by the viral protease PR, which is expressed either in Gag, Gag-Pol, or Gag-Pro-Pol fusion proteins. Thus, PR is responsible for cleaving itself out of a precursor protein, then making a number of other cleavages in these proteins.

Activation of the Protease

The processing of Gag and Gag-Pro-Pol precursors is intimately linked to assembly and budding, and is controlled so that the precursors are not cleaved until they are assembled. It is not certain how PR is regulated during assembly to begin cleaving its substrates. The structure of PR has revealed that the active enzyme is a homodimer (see Protease Structure and Function section), and thus its activation could be promoted by dimerization of the Gag or Gag-Pro-Pol precursor associated with assembly. As the virions form, one could imagine the high concentrations of the protein generating an active PR that would begin to cleave Gag and Gag-Pro-Pol, and would release the mature PR dimer as well. However, for the betaretroviruses like MPMV, this mechanism cannot explain the delay in processing. For these viruses, assembly occurs in the cytoplasm and should result in the establishment of a high concentration of Gag-Pro-Pol at that time. Yet cleavage does not begin in the cytoplasm, but rather is restrained until budding and export of the preformed virion particle. Thus, other unknown mechanisms, perhaps coupled to membrane association, must be responsible.

Various domains of Gag have been suggested to inhibit PR; conformational changes could relieve this inhibition. In the alpharetroviruses, a cleavage at the NC-PR boundary is required to release active PR, and thus activating this cleavage could serve as a trigger.⁷⁸ Similar cleavages at the p6*-PR boundary are important for full activation of the HIV-1 PR. Another possibility is the activation of the PR by a drop in the pH associated with virion release. It should be noted that the overexpression of PR in many artificial settings, both in bacteria and in animal cells, as a Gag-PR fusion or alone, can result in formation of highly active enzyme. The high level expression of PR is often toxic for cells, presumably due to its inappropriate action on many host proteins.

Protease Structure and Function

The retroviral proteases are aspartyl proteases with clear sequence similarity to members of the cellular family of aspartyl proteases.^{278,342} The three-dimensional structure of many proteases, including those from ASLV, HIV-1, HIV-2, SIV, FIV, and EIAV, have been determined by X-ray crystallography.^{313,387,412,620} The viral enzymes are small, typically containing about 100 amino acids, and are homodimers as isolated from virions. Each subunit contributes to the active site a single aspartate residue, lying in a loop near the center of the molecule. There is a long cleft at the interface between the subunits where the substrate lies; there are pockets to interact with each of the side chains of the substrate, conferring specificity to the enzyme. Each subunit has a flap consisting of an antiparallel sheet with a β -turn that covers the cleft. This flap moves out of the way to permit the binding of the substrate into the active site.

Retroviral proteases have a complex specificity for substrate peptides. The enzyme makes contact with approximately seven or eight side chains on the substrate, and thus can select its cleavage sites on the basis of at least these amino acids. The

cleavage sites tend to be within hydrophobic sequences, yet must lie in accessible and extended conformations. Some analyses of the various sites in Gag and Gag-Pol that are recognized by PR suggest that either one of two sequence motifs constitute a consensus site: one set has an aromatic residue or proline flanking the cleavage site, and the other set has aliphatic residues at these positions. Mutational analyses have allowed further definition of the residues on PR that make specific contacts to the substrate.

Protease Inhibitors

Studies of mutant viruses lacking PR demonstrated that the protease is essential for virus replication. Viruses lacking a functional PR can still express Gag and Gag-Pol precursors, and can mediate the assembly and release of immature virion particles. Thus, PR is not required for the process of virion assembly *per se*. However, these particles are noninfectious, and are blocked at an early step prior to the initiation of reverse transcription.^{118,279,299} Because of its essential role in virus infectivity, PR was appreciated early in the course of the AIDS epidemic as an attractive target for antiviral therapy. A number of molecules have been generated that can bind and inhibit PR, including peptide mimetics with uncleavable, nonsessile bonds at the cleavage site. Some are transition state analogs, and may have inhibition constants (K_i) in the nanomolar or subnanomolar range. These inhibitors have been extremely effective antiviral agents, and because they target a distinct enzyme and distinct step in the life cycle from the RT inhibitors, they have been particularly effective in combination with earlier drugs targeted at RT. The combination of three drugs that include a protease inhibitor is now the standard treatment for AIDS, and such highly active antiretroviral therapy (HAART) can keep virus loads below detectable levels in some patients for many years. Ultimately, however, point mutations in PR that confer resistance to the drugs can arise, allowing some virus replication in spite of therapy.

Processing of the Gag Precursor

During and after release from the cell, the Gag precursor is cleaved by the protease into a series of products present at equimolar levels in the virion. The number and size of the products vary considerably among the various viruses; the spumaretroviral Gag is exceptional in undergoing the fewest cleavages. A summary of the Gag products of some representative viruses are indicated in Table 47.4. There are many features of these products common to most of the retroviruses.

The Matrix Protein, MA

Beginning at the amino terminus, most Gags are processed to form a membrane-associated or matrix protein termed MA. The MA protein is thought to remain bound to the inner face of the membrane as a peripheral membrane protein, and can be crosslinked to lipid. MA may make contacts with the cytoplasmic tail of the envelope protein. When the precursor Gag is myristoylated at the amino terminus, the corresponding MA protein retains that myristate and is presumably bound tightly into the membrane. The compact structure of the MPMV MA protein has been elucidated by NMR.¹¹¹ The MA proteins of HIV-1 and SIV have been shown to form trimers in crystallization studies,^{38,497} and can contribute to the ability of a larger Gag precursor to form trimers in solution.³⁹³ The protein can

form extended sheets of trimers, with a large opening in the network. If similar structures were to form in a sphere, the surface could have openings into which the envelope tail may fit.

The Capsid Protein, CA

Gag proteins are cleaved to generate a large product serving as the major capsid protein, CA, in the virion core. The CA protein is relatively well conserved among Gags, and contains the only highly conserved motif among Gags, the so-called major homology region (MHR). The function of this motif remains uncertain; although mutations in the region affect virion assembly in some viruses,^{117,362,490,570} it is not absolutely required for this process, since the entire CA domain of ASLV can be deleted without blocking assembly. CA is thought to form the shell of the condensed inner core of the mature virus, making either a spherical, cylindrical, or conical structure, depending on the virion morphology. Image reconstruction of electron micrographs, coupled to the subdomain structures, have led to models for the packing of CA to form these large assemblies. The major CA–CA contacts must form after processing during the condensation of the virion core, and may be very different from the contacts that exist in the immature virion particle.

The CA protein can form dimers in solution, and recombinant proteins containing CA, or CA plus NC, can assemble to form higher-order structures consisting of either tubes, spheres, and in the case of HIV-1, cones.¹⁹¹ CA has also been studied after tethering sheets of the protein to membrane.²⁹ The CA protein has proved difficult to crystallize. Structures of the N-terminal and C-terminal fragments of the HIV-1, RSV, and EIAV CA were first determined,^{189,202,264,302} and only later were complete CA proteins visualized.¹⁹³ Mutants of HIV-1 CA with engineered potential to form disulfide crosslinks have allowed isolation and crystallization of stable hexamers, revealing a flower-arrangement with N-termini near the center and C-termini in radial extensions (Fig. 47.17).⁴⁸⁵ Very recent work has defined a similar arrangement of CA proteins in the pentamers that introduce curvature into the hexamers array.⁴⁸⁶

The Nucleocapsid Protein, NC

All Gag proteins except for those of the spumaviruses are cleaved to produce a nucleocapsid protein, NC, located near the carboxyterminus of the precursor. NC proteins are small,

highly basic proteins containing one or two copies of the Cys-His motif, Cys-X₂-Cys-X₄-His-X₄-Cys. These sequences bind a single Zn⁺⁺ ion avidly, and fold around the ion into a characteristic structure that is smaller and rather different from the better-known zinc finger structure. The structures of NC proteins in solution have been studied by NMR, revealing a tightly folded knuckle with disordered flanking sequences.^{298,392} The interaction with zinc results in the incorporation of substantial levels of Zn⁺⁺ into all retrovirus virion particles.

The NC protein in virions is closely associated with the viral RNA, probably coating the entire RNA molecule; the stoichiometry of binding is such that each NC molecule can bind to about 6 nucleotides of RNA. NC proteins bind non-specifically to heteropolymeric single-stranded nucleic acid

FIGURE 47.17. Structure of HIV-1 Gag CA hexamer. Top view of hexamers. Each subunit is colored distinctly. (Courtesy of Owen Pornillos, University of Virginia School of Medicine, Charlottesville, VA.)

with moderate affinity.⁶⁰³ However, NCs also exhibit specificity. Tests of binding to nucleic acids of defined sequence have shown that NCs bind poorly to poly(A), and most tightly to nucleic acids containing GT dinucleotides, especially alternating (GT)_n polymers.¹⁷⁴ In addition, NC has been shown to exhibit sequence-specific binding activity *in vitro* for nucleic acids containing the Psi region, required for packaging of the viral RNA.⁴⁴ A specific complex of the HIV-1 NC with a stem-loop derived from Psi has been studied by NMR. The resulting structure shows a number of specific contacts between hydrophobic residues of NC and bases in the four-nucleotide loop, and between basic residues and specific phosphates in the stem and loop.¹²⁹

NC proteins change the base-pairing properties of nucleic acids, and thus can have profound effects on the kinetics and thermodynamics of annealing. Under various conditions *in vitro*, NC can stimulate the dimerization of RNAs and duplex formation between tRNA and its complementary sequences at the primer binding site.⁶¹ Thus, NC can help promote primer tRNA placement during virion assembly.⁵⁰³ NC can also help melt out secondary structures, and may facilitate the movement of RT along the template during reverse transcription. In addition, it is clear that NC can bind to double-stranded nucleic acid, and is probably retained on the viral DNA after its synthesis by RT. NC mutants have been found that affect the course of DNA synthesis or DNA stability during the early stages of virus infection, suggesting a role in the processing of the DNA and protection of DNA from degradation.^{208,586} Finally, NC has been shown to promote the concerted integration of the two termini of the viral DNA into a target sequence (see Viral *att* sites section;⁸⁵).

An important class of inhibitors of virus infectivity and replication that act by targeting the NC protein have been identified.^{512,601} These compounds, disulfide-substituted benzamides (DIBAs), eject the zinc ion from NC and cross-link the cysteines via disulfide bonds. Virions treated with these compounds are potentially inactivated without disrupting the virion structure, and the course of virion assembly in infected cells is similarly blocked. Drug-resistant variants are not readily recovered.

Other Gag Products

Some retroviral Gag proteins, including those of the alpharetroviruses, betaretroviruses, and gammaretroviruses, contain one or more poorly conserved domains of 10 to 24 kDa lying in between MA and CA. The functions of these proteins is unclear. The ASLV p2 protein, the MuLV p12 protein, and the MPMV p24 protein contain a PPPY motif that plays an important role in late stages of virion assembly (see The L domain section). The MuLV p12 protein has also been shown to play a role in the early stages of infection.^{119,659}

In the lentiviruses, a p6 domain is present at the carboxy-terminus. The role of p6 is unclear, though it contains the late or L domain and thus may be important in virion release. It also is required to mediate the incorporation of Vpr into virion particles, perhaps by providing a direct docking site. Proteins can be targeted to virions by generating Vpr-X fusions, which are incorporated into lentiviral virions in a p6-dependent manner.

Processing of the Gag-Pro-Pol Precursor

At the same time that the Gag precursors are cleaved during virion maturation, the Pro and Pol region of the Gag-Pro-Pol

FIGURE 47.18. Cleavage patterns during the processing of the Gag-Pol fusion proteins of various retroviruses. The structure of the mature cleavage products found in the virion particles are shown aligned with their location in the precursor.

precursor is also cleaved, giving rise to the PR, RT, and IN products. The Pro- and Pol-containing precursors of different viruses are cleaved in diverse patterns (Fig. 47.18). In the gammaretroviruses, the Pol region is processed by complete digestion to form PR, RT, and IN. In the alpharetroviruses, the Pol region is cleaved to produce a heterodimeric RT with a larger β subunit and a smaller α subunit. The larger β subunit contains both RT and IN domains. It is not clear whether the IN domain in the context of this subunit performs an important function, although it is responsible for a weak nuclease activity associated with RT.²⁰⁵ A portion of the Pol precursor undergoes an additional cleavage to produce the α subunit of RT (an aminoterminal fragment of the β subunit), and the separate IN protein. In the lentiviruses, Pol is processed to give rise to PR, a heterodimeric RT, and IN. However, the RT of these viruses is not identical to the heterodimeric RT of the alpharetroviruses. Here the IN domain is fully removed from RT. One RT subunit remains intact (for HIV-1, this is the p66 subunit), and the other subunit undergoes an additional cleavage to remove a carboxyterminal domain (to form the p51 subunit). The functional significance of the different subunit structures of these various RTs is unclear, since they all perform a very similar set of reactions during virus replication. The processing of Pol precursors may be associated with the activation of the DNA polymerase of RT. In the alpharetroviruses, the immature Gag-Pol protein has very low DNA polymerase activity; its maturation results in a large increase in activity.^{116,564} However, the immature Gag-Pol protein of MuLV and HIV-1 has high DNA

polymerase activity, and there is only a very modest increase upon maturation.¹¹⁸

The Gag-Pro-Pol precursor of the betaretroviruses and the nonprimate lentiviruses is also processed to produce the dUTPase protein, DU. In the betaretroviruses, the *pro* ORF encodes both DU and PR; in the nonprimate lentiviruses the enzyme is encoded in the *pol* ORF, and DU lies in between RT and IN in the polyprotein. This enzyme acts to reduce the levels of dUTP that could otherwise be incorporated into viral DNA. Mutants of FIV lacking the function show increased rates of mutation during replication,³²⁴ and similar mutants of CAEV tend to accumulate G-to-A substitution mutations⁶⁰² presumably due to incorporation of dU residues that are subsequently read as dT.

Processing of the Env Precursor

The major proteolytic cleavage of the Env protein to form the SU and TM subunits is performed during its transport through the ER and golgi by host proteases termed furins. This cleavage is essential for virus infectivity,^{376,467} and is thought to induce substantial rearrangements of the polypeptide chain. The TM subunit remains embedded in the membrane, consisting of an extracellular domain, a membrane-spanning segment, and a cytoplasmic tail. The SU subunit lies wholly outside the cell, and after its incorporation into the virion particle, wholly on the extravirion surface. It is held onto the virion by contacts to TM, most often by noncovalent bonds, though disulfide links may occur in some viruses. SU is heavily glycosylated; the presence of at least some of these sugars is important for virus infectivity. Perhaps the most important function of this heavy glycosylation is to hide the peptides on the surface of Env from neutralizing antibodies that would otherwise have access to the virion surface. In addition, palmitoylation of the Env proteins of many viruses is essential for function.^{329,424,522}

The Surface Subunit SU

For most viruses the major receptor-binding site is located in hypervariable sequences on the SU subunit, so that SU is a major determinant of host range. Chimeric SU proteins can be generated to demonstrate that the receptor utilization function maps to specific regions of the protein. The key regions of the avian retroviral Env proteins have been similarly defined by selecting for changes in host range *in vivo*; these studies show that very small changes can result in the use of new receptors. The structures of two SU proteins have been determined at high resolution: a fragment of MuLV SU,¹⁶³ and a fragment of the HIV-1 SU bound to its receptor CD4.^{310,514} These structures suggest that the receptors make contacts to the envelope in shallow pockets that may not be readily bound by antibodies.

The Transmembrane Subunit TM

The TM subunit contains the so-called fusion peptide at its aminoterminal. TM is thought to play the major role in fusion of the virion and host membrane. Many TM mutations are defective for membrane fusion. However, mutations blocking fusion can lie in SU as well. The entire Env protein probably acts as a unified machine to mediate fusion, with complex interactions between the subunits and with major movements of the subunits during the fusion process. The fusion peptide of TM may simply insert into the host membrane or it may make contacts to proteins. The major contacts for oligomer

formation of Env are thought to lie in TM; isolated TM proteins form trimers in solution and in crystals.^{163,164,297,361} The trimer is held together by a modified leucine zipper motif that bridges the monomers via hydrophobic interactions.

It is possible to separate the two major functions of the Env protein onto two different molecules that cooperate to mediate these steps. Thus, the receptor binding function can be mediated by one Env protein, and the membrane fusion function can be mediated by another Env. This is apparent in the ability of two Env proteins to complement in mixed oligomers.⁵⁰² It is also demonstrated by the ability of a wild-type Env to provide the membrane fusion function for a chimeric Env that on its own can only mediate cell-surface binding.

The TM subunit of the MuLVs undergoes a second cleavage during virion assembly that is mediated by the viral protease, PR. This step removes a short sequence called p2E, or the R peptide, from the carboxyterminus of TM.²¹⁴ The cleavage step may require presentation of the tail to the protease, or some conformational change in the tail, that is mediated by Gag proteins; alterations in the MA or p12 Gag proteins can modulate the cleavage of TM.^{291,659} Astonishingly, the cleavage is necessary to activate the fusogenic activity of the envelope protein and thus for virus entry.^{71,501} Mutants in which the tail is truncated at the site of cleavage are constitutively activated for fusion, and these viruses induce dramatic syncytia in receptor-positive cells. Mutants in which the tail is not removed are inhibited for fusion, and particular residues can be shown to be required.⁶⁴⁸ How the cytoplasmic tail inhibits the fusogenic activity of Env is very much unclear.

In a similar way, the cytoplasmic tails of the TM of M-PMV and EIAV are processed by the protease. In the case of M-PMV, the presence of the intact tail is necessary for efficient incorporation of Env into the virion. The replication of some viruses in host cells of foreign species can select for alterations and truncations of the TM tails. The selective advantage conferred by this truncation is not well understood, though various aspects of Env function seem to be enhanced by this truncation.⁶⁷³

Morphological Changes upon Virion Maturation

The maturation of retrovirus particles is a complex process required for the formation of an infectious virus. The particles that are initially assembled either at the plasma membrane (by most retroviruses) or in the cytoplasm (by the betaretroviruses) have a characteristic immature morphology: the particles are round, and stain with an electron dense ring and a relatively electron lucent center. After release from the cell, the morphology changes to a more condensed structure, with a central core largely detached from the surrounding envelope. In the alpharetroviruses, gammaretroviruses, and deltaretroviruses, the core is spherical and concentric with the envelope; in the betaretrovirus the core is spherical but eccentrically placed within the envelope; in the lentiviruses the core is cylindrical or conical, with thin connections to the surrounding shell. In the spumaviruses the morphology does not change dramatically after assembly.

Mutant viruses lacking the protease show little change in morphology. Thus, cleavage of Gag and Gag-Pol is required to restructure the virion into the mature form.²⁷⁹ The changes in morphology visible in electron micrographs are probably associated with major rearrangements of the Gag proteins. The physical properties of the virus change dramatically upon maturation. Whereas the immature core is very stable to nonionic detergents

FIGURE 47.19. Reconstruction of the conical core of a single HIV-1 virion. Hexamers of the HIV-1 CA protein (purple) were organized in a folded array. Curvature was introduced by the asymmetric placement of pentameric defects (red) at each end of the cone. (Courtesy of Wes Sundquist, University of Utah, Salt Lake City, UT.)

and harsh conditions, the mature virion core is relatively labile. This change may reflect the inability of the immature virion, and the acquired ability of the mature virion, to uncoat upon infection of new cells and initiate reverse transcription.

Structure of Virion Core: CA Packing

After maturation, the Gag proteins rearrange to form the distinctive virion core, comprised of the CA protein surrounding the dimeric viral RNA condensed with the NC protein. The core is visible by electron microscopy as an electron-dense structure inside an electron-lucent area surrounded by a spherical shell and lipid envelope. The shape of the core is characteristic of the virus genera: round for the alpha- and gammaretroviruses, cylindrical for the betaretroviruses, and conical for the lentiviruses. Image reconstruction and X-ray crystallography studies of CA assemblies suggest that CA forms a hexameric array.^{191,302,330} The hexamers can form a two-dimensional lattice,¹⁹⁰ or long helical tubes or cones¹⁹¹ or spheres²¹⁸ *in vitro*. The N-terminal domains form external hexameric rings, and

the C-terminal domain forms internal dimer contacts to link together adjacent hexamers. While hexamers can form tubes without distortion, the curvature needed to close the ends of a cylinder or cone, or to form a sphere, is thought to be generated by introducing pentamers into the otherwise hexameric array.^{194,330} Asymmetric placement of the pentamers can create the cone-shaped core of the HIV-1 virion (Fig. 47.19).

RESISTANCE TO RETROVIRUS INFECTION: HOST RESTRICTION FACTORS

Several loci in the mouse genome have long been known to provide dominant resistance to the MuLVs, including *Fv1*^{336,477} and *Fv4*.⁵⁷⁴ Recently a number of novel host genes have been identified that also confer virus resistance to otherwise sensitive cells (for reviews, see 52,203). In some cases, these genes were identified as the targets of viral proteins that serve to inactivate the host restriction system; mutation of the viral functions then revealed the underlying restriction. In other cases, they were identified as the basis for a species-specific virus resistance: for example, the resistance to HIV-1 exhibited by various nonhuman primates. Collectively, these restriction systems target nearly all steps in the virus life cycle (Fig. 47.20). Although

FIGURE 47.20. Sites of inhibition of the virus life cycle imposed by various restriction factors. A schematic of the virus life cycle is shown with steps in replication indicated on the left. Timing of blocks by different restriction factors is indicated on the right.

these factors are typically not effective in blocking wild-type viruses in humans, there is hope that they can somehow be activated or enhanced to provide antiviral protection.

Receptor Blockade by *Fv4*

One gene present in Japanese wild mice, identified as conferring resistance to Friend MuLV, has a simple mode of action: the *Fv4* gene restricts virus replication by blocking the ecotropic virus receptor.^{574,589} The *Fv4* locus corresponds to a defective endogenous provirus that encodes an Env protein fragment; the product downregulates the receptor and renders mice resistant to infection by exogenous viruses.^{252,303}

Early Block to Infection by *Fv1*

The *Fv1* gene was identified in several inbred mice in the early 1970s as mediating resistance to leukemogenesis by the Friend MuLV.^{336,477} Two naturally-occurring alleles provide resistance: the *Fv1*^b allele (in Balb/c mice) allows replication of so-called B-tropic viruses but blocks N-tropic viruses, while the *Fv1*^a allele (in NIH swiss mice) allows replication of N-tropic viruses but blocks B-tropic viruses. Resistance is dominant in heterozygous animals. The tropism of the MuLVs can be characterized by their ability to replicate on cells of particular genotypes: N-tropic viruses grow only on *Fv1*^{nm} cells, B-tropic viruses grow only on *Fv1*^{bb} cells, and NB-tropic viruses grow on both. The determinants of viral tropism lie in the *gag* gene, and affect a small sequence of the CA protein.^{63,242,440,518,563} The block to infection in resistant cells is at an interesting stage: largely after reverse transcription and before nuclear entry and provirus integration.^{270,649} Curiously, the block to integration that is observed for a particular virus and cell combination *in vivo* is lost when the PIC is extracted and tested for its ability to integrate *in vitro*.⁴⁹¹ The *Fv1* gene was identified as a unique member of an endogenous retrovirus gene family, with close similarity to the *gag* genes of the HERV-L family.⁵⁰ The two alleles differ by a few point mutations and a different carboxyterminal region. Thus, the intracellular expression of this variant Gag protein can somehow interact with the incoming PIC and its associated CA protein to block infection.

Early Block to Infection by Trim5a

Human and many other mammals are resistant to N-tropic MuLVs via an activity dubbed Ref1.^{48,596} This block is similar to that induced by the murine *Fv1*^b gene (both are determined by residue 110 of the CA protein), although it acts earlier, before viral DNA synthesis. Rhesus macaques and other non-human primates manifest a similar block to HIV-1 infection in the early steps of the life cycle, also determined by CA, and originally called Lv1.^{115,399} These blocks were saturable: exposing cells to high levels of a restricted virus could overcome, or “abrogate,” the block to infection by a second virus.^{48,227,301} The gene responsible for these blocks encodes TRIM5a, a member of a large protein family known as the RBCC (Ring, B box, coiled-coil) or TRIM (tripartite sequence motif) proteins.^{230,285,469,571} The mechanism of action of TRIM5a in blocking virus infection is not clear, but likely involves binding to the CA protein of the incoming virus.⁵⁴⁴ Recently a structure of a TRIM5a lattice superimposed over a hexameric sheet of CA protein has been visualized, suggesting that a highly multimeric form of TRIM5a might recognize the multimeric form of CA present in the virion core.¹⁹² Trim5 activity can be enhanced

by overexpression of SUMO-1, the small ubiquitin-like modifier protein, and requires the presence of two SIMs, or SUMO-interaction motifs.¹⁸ A simple model explaining these findings is that TRIM5 binding to CA is enhanced by CA SUMOylation.

The critical residues of HIV-1 CA for TRIM5a recognition lie in the cyclophilin A binding loop,^{188,605} and complex interactions between CA, TRIM5a and cyclophilin A may determine virus sensitivity.^{229,597} A remarkable confirmation of the functional interrelationships between these proteins is the finding that in a new world primate, the owl monkey, the TRIM5 gene is interrupted by the transposition of a cyclophilin A pseudogene and expresses a TRIM-Cyp fusion protein.^{419,532} A similar, but independently arising, gene fusion has been found in other primate lineages.^{333,611} These fusion proteins confer potent resistance to viruses that retain a cyclophilin A binding site in their CA proteins. A plausible model for the action of all these factors is a premature disruption of the capsid soon after viral entry. Restriction by TRIM5a may occur in two steps, with an initial proteasome-dependent step before reverse transcription, then a proteasome-independent one after reverse transcription.⁶⁴¹

Recently, TRIM5a has been shown to play a role in the induction of interferon production by stimulating synthesis of unlinked polyubiquitin chains.⁴⁷¹ Thus, another antiviral function of TRIM5a may be to signal interferon production in response to an incoming viral core; this function seems to be independent of its direct antiviral activity.

Deamination of Viral DNA by the APOBECs

A major mechanism of resistance to HIV-1 is provided by the deamination of cytosine residues in the minus strand of the viral DNA formed during reverse transcription.^{225,549} The main enzyme responsible for this activity in primates is APOBEC3G, one of a family of cytidine deaminases that includes APOBEC1 (a regulator of ApoB mRNA expression) and AID (activation-induced cytidine deaminase, used in immunoglobulin class switching and hypermutation of immunoglobulin genes during affinity maturation). The family member APOBEC3F is also effective at blocking infection. APOBEC3G is packaged into virions and during subsequent infection can deaminate as many as 4% of the C residues of the viral DNA minus strand, resulting in both DNA destruction and G-to-A hypermutation of the surviving plus strand DNAs.^{224,319,366,665} In addition to its deaminase activity, APOBEC3G may independently trap or inhibit viral DNA synthesis during infection.⁴¹⁶ APOBEC3G is apparently targeted to the virions by interactions with NC and/or viral RNA.

This potent block to infection mediated by the APOBECs is counteracted in human cells by the HIV-1 Vif protein, which drastically reduces the levels of APOBEC3G and F in the infected cell and prevents their incorporation into virions. Vif binds APOBEC3G and F, and blocks them either by inducing their proteasomal degradation via the Cullin5-SCF ubiquitin ligase complex, by inhibiting them directly, or by blocking their translation. The APOBECs of many nonhuman primates are not recognized by HIV-1 Vif; as a result, these species can block HIV-1 infection. In addition, the family member APOBEC3B, which has potent antiviral activity in cell lines, is resistant to HIV-1 Vif.¹³⁸ It is not clear why this isoform is not expressed adequately in lymphocytes to protect humans from infection.

Another host enzyme, uracil N-glycosylase (UNG), may collaborate with the APOBECs to promote degradation of the

viral DNA. This enzyme is also packaged into virions, and recognizes and removes uracils in the DNA, the product of deamination of cytidines, leaving an abasic site. This would block normal reverse transcription and lead to destruction of the viral DNA. However, the HIV-1 gene product Vpr can mediate the inactivation of UNG and the related SMUG enzymes, again probably via ubiquitin ligase-triggered proteosomal degradation.⁵³⁷

Blocking Early Events in Monocyte Lineage Cells by SAMHD1

Dendritic and myeloid cells exhibit a potent restriction of HIV-1 replication that prevents the normal accumulation of viral DNAs in the cytoplasm in the early phase of infection. The block can be counteracted by delivery of the Vpx protein encoded by certain strains of SIVs. Recent work has identified SAMHD1 as the mediator of the block.^{245,311} Vpx induces proteosomal degradation of SAMHD1 and thereby allows virus infection.

Elimination of Viral RNAs by ZAP

A block to MuLV infection was initially identified in a screen of cDNA overexpression libraries for genes that confer virus resistance. The product of a rat gene, dubbed ZAP (for zinc finger antiviral protein), blocks viral gene expression by eliminating viral RNAs from the cytoplasm of the infected cell.¹⁹⁵ ZAP contains four CCH-type zinc fingers that bind directly to viral RNA²¹⁹ and targets the RNA for destruction by the RNA exosome.²²⁰ Remarkably, ZAP expression also renders cells resistant to infection by a number of alphaviruses, including Sindbis, Semliki Forest virus, and Venezuelan equine encephalitis virus,⁵¹ and by Ebola virus.

Trapping Virion Particles on the Cell Surface by Tetherin

HIV-1 mutants lacking the *Vpu* gene are poorly able to replicate in certain cell lines, with the major block being at the time of virion release from the infected cell surface. The inhibition was traced to the cell-surface expression of a protein dubbed tetherin, which traps the virion particles and prevents viral spread to neighboring cells.^{414,468} Tetherin can similarly inhibit spreading infections by many enveloped viruses.²⁷³ The Vpu protein of wild-type HIV-1 binds to tetherin and inactivates it; this may be achieved either by sequestering it, preventing its delivery to the cell surface, or by directing its ubiquitinylation and degradation.^{142,149,231,256,365}

MicroRNA or siRNA-Mediated Inhibition of Viral Gene Expression

Retroviruses may be inhibited by host microRNAs,^{114,318} and HIV-1 has further been suggested to encode microRNAs that suppress the RNA silencing machinery of the cell,⁴⁰ though these observations are controversial. The significance of these observations for replication *in vivo* remains to be determined.

RETROVIRAL DISEASES

The Varied Effects of Retroviral Infection

Retroviruses cause an extremely wide range of responses in infected animal hosts. Discussion of retroviral pathogenesis begins with a little-appreciated but important point: retroviruses in general are surprisingly benign. The vast majority of

the replication-competent retroviruses are not cytopathic, and the infection of cells cause remarkably little impact on their replication or physiology. The morphology, control of cell division, and doubling time of cells in culture are not significantly changed after infection. Once a chronic infection is established, only a relatively small amount of the cellular metabolism is committed to virus expression: typically a few percent of the cellular mRNA and protein are viral, and thus the cell can perform its normal functions and survive for its normal lifespan. Animals show few acute effects upon infection. Animals do become viremic, and a vigorous immune response is often mounted that can reduce the levels of virus production. However, infected mice or birds may live relatively normal lives for many months or years; it therefore is appropriate to consider the viruses as relatively benign parasites. It is noteworthy that the virus is not eliminated but only suppressed by the immune response, and low-level viremia usually persists in infected animals for life.

Retroviruses often do, however, cause disease. The chronic viremia of the replication-competent retroviruses is tantamount to high-level mutagenesis of infected cells, for each infection event is associated with a proviral insertion that constitutes a mutation. Eventually the odds are that a cell will suffer an insertion that alters the normal control of cell division or cell survival, and abnormal proliferation of this cell results in tumorigenesis. Many retroviruses cause disease in this way, including the so-called “slow leukemia viruses” and agents such as MMTV. A few retroviruses, however, are more pathogenic: a small minority of the retroviruses are directly cytopathic, and many of the infected cells are killed. These agents can thus destroy the infected tissues and directly damage their function. These include the cytopathic avian viruses and, probably, the AIDS virus, HIV-1. Finally, a special class of retroviruses exists, the so-called “acute transforming viruses,” that can induce a rapid tumor formation. These viruses were among the first filterable oncogenic agents ever discovered; their dramatic effects were a major motivation for the intense study of all the tumor viruses throughout the twentieth century. We now understand that these agents are transducing viruses; the replication of retroviruses allows for recombination events between viral and host sequences that move genes onto the viral genome. These viruses carry and express host genes at inappropriate levels, in inappropriate cells, and often with drastic alterations in gene structure. If the gene product so expressed by the virus is mitogenic or antiapoptotic, the result can be a potent alteration in the physiology of the infected cell. These acute transforming viruses can thus initiate a highly aggressive tumor very efficiently and with minimal latency, because each infection of a cell has the high potential to initiate an oncogenic transformation event. Most often the acquisition of the host gene comes with a loss of a viral gene essential for its replication; as a result, these viruses are often replication defective and depend on a helper virus, usually a replication-competent leukemia virus, for their transmission to new cells. Each of these classes of pathogenic viruses will be discussed in the following sections.

Diseases Caused by the Replication-Competent Retroviruses

The typical pathology of many of the simple replication-competent retroviruses is the development of leukemia or lymphoma after a very long latency. For this reason these agents are often called the slow leukemia viruses; examples are found in rodents, including the many MuLVs, and in birds, including

the avian leukemia-leukosis viruses. The symptoms eventually begin with a lymphoid hyperplasia,⁵⁶⁶ which may be directly attributed to the immune response. Not all affected cells are infected, and the proliferating cells may be stimulated by cytokines that are released in response to the infection.⁷⁰ These cells may include a preleukemic state of partially transformed cells. There may be some cell killing due to enhanced apoptosis in these early stages,⁶² though the mechanism of the apoptosis and the relationship to tumorigenesis is unclear. A subset of these expanding cells progresses to frank leukemia, which ultimately can be fatal in susceptible animals. These observations strongly suggest that leukemogenesis is a multistep phenomenon, and it is also likely that the virus plays a role at more than one of these steps. The cell type transformed by the virus can be very narrowly defined, or more broadly variable, but will depend strongly on viral determinants. For example, the ASLV group of viruses typically causes a bursal or B-cell lymphoma in birds; the Moloney MuLV causes a T-cell leukemia; the Friend helper MuLV causes an erythroleukemia; and MMTV causes a mammary epithelial tumor.

In some species and settings, the infecting virus is the proximal agent of disease; such is the case with infection of rats by the Moloney MuLV. However, the course of leukemogenesis in mice and other animals is often associated with the appearance of recombinant retroviruses derived from the parental infecting virus and endogenous sequences present in the germ line.^{93,162} The recombinant viruses are often the true or proximal pathogens. These viruses are heterogeneous in structure and phenotype, but most contain substitutions of the *env* gene and LTR that confer novel properties to the initial virus. Some of the viruses arising in mice can be detected through an expanded host range, as an ecotropic virus acquires *env* sequences that allow infection through the xenotropic or dual-tropic receptors; these viruses are often termed MCF viruses, for mink cell focus forming viruses. The range of cell types and the replication ability of the input virus can be expanded by recombination to significantly enhance the incidence of leukemia and shorten the latency period to disease. The donor sequences for these recombination events are not all universally present in a given species but are highly variable from strain to strain. The presence or absence of suitable endogenous proviruses in the germline that provide the sequences needed for recombination can control the severity and course of disease.

Leukemogenesis by Insertional Activation

The most common mechanism of action of the replication-competent viruses in initiating tumors is termed proviral insertional mutagenesis, leading to the activation of endogenous proto-oncogenes.^{232,422,464} During replication in the infected animal, an enormous number of cells are infected, acquiring new proviral DNA insertions at near-random sites. Each of these insertions constitutes a somatic mutation, and thus retrovirus infection can be thought of as similar to a massive exposure to a potent mutagen. The vast majority of the insertions are harmless, causing no significant change in host gene expression. The majority of those that do disrupt genes simply create a recessive mutation at one allele out of two present in the cell, again causing no significant change in the overall pattern of gene expression. But very rarely, a provirus insertion can create a dominant-acting mutation that profoundly alters the physiology of the cell. When a provirus integrates near a gene that controls growth, altering its expression, the cell may

proliferate and ultimately form a clonal tumor in which all cells contain the provirus integrated at the same site.

A large number of cellular genes have been identified as potential targets for insertional activation in retrovirus-induced tumors. Among the most notable are an array of transcription factors, including *c-myc*, *N-myc*, *c-myb*, *Fli1*, *Fli2*, *Ets1* (*Tp11*), *Evi-1* (*Fim3*), *Bmi1* (*Flvi2*), and *Spi1* (*PU.1*); a number of secreted growth factors, such as *Wnt1* (*Int1*), *Wnt3* (*Int4*), *Int2* (*Fgf3*), and *Fgf8*; growth factor receptors, including *c-erbB*, *Int3* (*Notch4*), *Mis6* (*Notch1*), *c-fms* (*Fim2*), the prolactin receptor, and *Fit1*; and genes implicated in intracellular signal transduction pathways, such as the serine/threonine kinases *Pim1* and *Pim2*. Many of these genes are also known to be involved in or implicated in tumorigenesis in other settings, either when transduced on retroviral genomes or when activated by more conventional mutations. However, a number of the proto-oncogenes have been identified only by virtue of having served as target sites during tumorigenesis by leukemia viruses; thus, this route has made important contributions to the list of known proto-oncogenes.

The patterns of activation of these proto-oncogenes by retroviral insertion are highly varied. At least four distinct mechanisms have been observed (Fig. 47.21).

- **Promoter insertion:** The provirus may insert upstream of the gene or within the gene, and in the same transcriptional orientation as the gene. Transcription beginning in the 3' LTR reads into the gene and results in high-level expression of a transcript with R-U5 sequences at the 5' end. The resulting transcripts may be similar to the natural transcripts, but may be longer or truncated relative to the normal mRNAs.
- **Enhancer insertion:** The provirus may insert either upstream or downstream of the gene, and in either orientation relative to the gene. The insertion brings the powerful transcriptional enhancers present in the U3 regions of the two LTRs into close proximity of the gene, activating the endogenous promoter elements. While the levels are inappropriately high, the structure of the resulting transcript is normal.
- **Posttranscriptional stimulation of expression:** The provirus may insert downstream of the coding region and stabilize the formation of an mRNA. The provirus may provide a polyadenylation signal that enhances the formation of stable transcripts; or the insertion may remove RNA destabilization signals in the 3' UTR that would normally mediate the rapid turnover of the RNA. These mechanisms can result in inappropriately high steady-state levels of the mRNA and protein products.
- **Readthrough transcription:** The provirus inserts upstream or in the gene, but transcription initiates in the 5' LTR, reads through the provirus, and continues into the gene. The formation of such transcripts is often enhanced by mutations in the provirus, such as loss of the 3' LTR. The transcripts may be spliced aberrantly in complex patterns.

Insertional activation of a proto-oncogene by a provirus is not sufficient on its own to fully transform a cell, but represents only one step in a progression to a frank leukemia or tumor. Other mutations are usually required; these mutations can be point mutations in other proto-oncogenes or loss of function mutations of tumor suppressor genes. In some retroviral tumors, more than one oncogene can be activated by insertion of separate proviruses. Similarly, an acute transforming genome is usually not sufficient to transform a cell in one

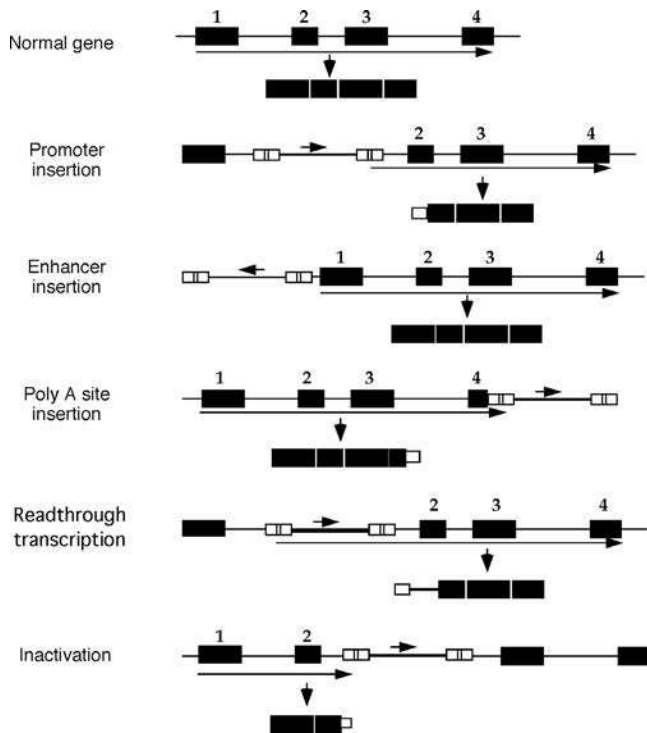

FIGURE 47.21. Genetic alterations in target gene expression induced by retroviral insertional mutagenesis. Various changes in normal gene expression that have been observed upon insertion of retroviral DNA are diagrammed. A target gene containing four exons is used in these examples (*top*). Promoter insertion: Insertion of the provirus in the same transcriptional orientation in the first intron is shown to result in the formation of a new mRNA initiated in the 3' LTR and extending into the downstream exons. Enhancer insertion: insertion upstream of the gene, in this case in reverse orientation, is shown enhancing the expression from the natural promoter. PolyA site insertion: insertion at the 3' end of the gene in the forward orientation is shown providing a polyA addition signal, increasing the levels of a prematurely truncated mRNA. Leader insertion: insertion of the provirus in the same transcriptional orientation is shown to result in the formation of an RNA initiating in the 5' LTR, extending through the provirus, and into downstream exons. Splicing results in the retention of only the viral leader on the chimeric mRNA. Inactivation: insertion is shown causing premature end formation of the mRNA, resulting in the formation of an inactive fragment.

step, and additional mutations must arise. In some tumors induced by a replication-defective transforming virus, the helper virus may provide such mutations by its own insertional activation event.

Gene inactivation, as opposed to gene activation, is also an important event in some tumors. Retrovirus insertion can frequently disrupt gene expression to effectively produce a null or hypomorphic mutation. These mutations are normally silent, since a second allele would be expected to continue to express a functional gene product. However, if the host animal is already heterozygous due to an inherited germ-line mutation in one allele, or if the insertional inactivation is coupled to a loss of the other allele by other means, the net result can be homozygous loss of function. When the target gene is a tumor suppressor, the consequence is the promotion of tumorigenesis.

Viral Determinants of Pathogenicity

Several viral genes and sequences can affect the incidence and severity of retroviral disease. The viral LTR contains the most important determinants of leukemogenicity and of the cell tropism for transformation. The enhancer and promoter elements of the LTR are responsible for proto-oncogene activation; their relative transcriptional activity thus controls the transforming ability of many viruses. If these elements are strongly tissue- or cell type-specific, the virus will be most competent for transformation of those cells in which the LTR is most active. A variety of viruses show profound tropisms for transformation that are controlled in this way.^{64,345,451} For example, the promoter of the Moloney MuLV is most active in T cells, and the virus shows strong tropism for the formation of T-cell leukemias. The Friend helper virus LTR contains an enhancer that is most active in erythroid cells; the virus is correspondingly highly tropic for erythroid cells.⁶⁵ The promoter of MMTV contains glucocorticoid response elements that provide high-level expression only in cells with high levels of the glucocorticoid receptor and only when exposed to glucocorticoids; as a result, MMTV is specific for mammary tumors.²¹⁷ Variant betaretroviruses, such as the thymotropic DMBA-LV virus, show selectivity for T cells that is probably attributable to changes in the LTR. Determinants of leukemogenicity have also been mapped to *gag*, *pol*, and *env* genes, though it is not clear what aspects of their functions are required in most cases. It may be that vigorous replication *in vivo* is the simple key feature of a highly transforming leukemia virus. There may also be *trans*-acting functions encoded by the leukemia viruses that modulate expression of specific host genes, but their roles are uncertain. The murine and feline leukemia virus LTRs encode short RNAs that can *trans* activate host genes, apparently through activation of an AP-1-like activity.

Other aspects of infection, distinct from the genetic makeup of the virus or host, can modulate the pathology associated with infection; even the route of entry of the virus can affect the disease course, presumably by determining the initial cell types infected and the route of virus spread.

Other Retroviral Diseases

A new gammaretrovirus, the xenotropic murine leukemia virus-like virus (XMRV), was first identified in familial prostate cancer cell lines, and subsequently detected in a subset of prostate tumor samples.⁶⁰⁴ The virus is similar in sequence and properties to the mouse xenotropic MLVs. XMRV was subsequently suggested as a potential cause of chronic fatigue syndrome in humans.³⁴³ Recent work has strongly suggested that the virus arose during passage of prostate tumors in nude mice by recombination events between two endogenous mouse retroviruses, and that most reported isolates are laboratory contaminants.⁴⁵² Whether humans are infected by replicating xenotropic MLVs remains controversial.

Cytopathic Viruses

Some viruses show distinctive pathogenicity mediated by specific gene products. Cas-Br-E MLV is a well-studied murine virus that induces a hind-limb paralysis with significant neuronal loss in the absence of an inflammatory response.⁴⁸⁷ Both neurons and glial cells accumulate vacuoles. The virus targets endothelial cells and microglial cells in the brain. It is likely that the infection of the microglial cells is most crucial to disease

induction. Infection may impair or block the neuronal support function of these cells, resulting in loss of neurons, though the mechanism of neuronal cell death is unclear. It is possible that the expression of the Env protein is toxic. The major determinant of pathogenicity is in the SU subunit of the Env protein.^{354,453} A number of other MuLVs, such as the ts1 mutant of the Moloney MuLV TB strain,⁶⁴⁰ can cause neurologic symptoms, including hind-limb paralysis and spongiform encephalomyelopathy.⁵³ In these cases, the SU protein is thought to be important as well. TR1.3, a Friend-related MuLV, is a neuropathogenic virus that induces fusion of capillary endothelial cells, leading to a hemorrhagic stroke syndrome. The crucial determinant in the virus is a tryptophan residue at position 102 of the SU protein. In some viruses, the LTR is also likely to play a role in disease induction,^{133,454} perhaps by determining the level of expression and the ability to spread efficiently and access the primary target cell.

A number of the ASLV group of viruses are cytopathic,⁶²⁵ and can cause an acute wasting disease characterized by poor growth, anemia, and immunosuppression associated with atrophy of the bursa and thymus.⁵⁰⁵ The disease probably reflects the ability of these viruses to lyse infected cells. The isolation of the ALV receptor for the subgroup B viruses and its identification as a member of the TNF receptor family suggests the possibility that the binding of Env to the receptor is directly triggering an apoptotic response. The cytopathic and noncytopathic viruses seem both to be able to trigger similar responses, however, so that it is not clear at this time what aspect of the interaction might be necessary and sufficient for cell killing. The vigorous replication of the virus, and an ability to mediate high-level reinfection before superinfection resistance appears, may also be significant determinants of cytopathology.

Yet another disease caused by a variant virus is the feline acquired immunodeficiency syndrome, or FAIDS. This disease was originally associated with a complex mixture of FeLV isolates. The agent responsible was shown to be an FeLV with mutations affecting the SU subunit of the *env* gene. The mutant FeLV is incapable of establishing superinfection resistance, and thus large amounts of unintegrated viral DNA accumulate during superinfection, ultimately leading to high expression of viral gene products and causing cell lysis.

The lentiviruses cause an array of important diseases in animals and humans, most notably AIDS. The major cause of disease is probably cell killing, but the most important target cells and mechanism by which infection leads to cell death are not clear. The very high level of gene expression mediated by HIV-1 infection in some cell types may be a crucial aspect of the cell killing,⁵⁶⁰ but the key viral gene products remain obscure. HIV-1 infection eventually leads to depletion of CD4-positive cells and thus to immunodeficiency, culminating in severe opportunistic infections. The lentiviruses also cause a number of other pathologies, including neurologic disease, that are poorly understood. These diseases will be discussed in Chapter 50.

Stimulation of Host Cell Proliferation

MMTVs lead to the formation of mammary tumors through the insertional activation of a number of proto-oncogenes. However, unlike other simple retroviruses, MMTVs carry an additional gene termed *sag*, for superantigen, that is important for disease induction (see 107 for review). Sag proteins bind to

MHC class II molecules in regions that are common to molecules with many different binding specificities, and thus can activate as many as 10% of all T cells.

The *sag* gene is located in the U3 region of the MMTV LTR and encodes a low-abundance glycosylated membrane protein.⁶⁷ The protein must be proteolytically processed for proper export to the cell surface. Importantly, expression of a functional Sag protein by MMTV is required to establish infection in an animal. The virus is normally transmitted in mother's milk to newborn mice, infects B cells in the Peyer's patch, and induces a vigorous Sag-mediated stimulation of T cells. There follows a B-cell response that provides a large pool of susceptible B cells for the virus¹⁶; it is these cells that then carry the virus to the mammary gland. The infection of the mammary epithelial cells ultimately leads to transformation of these cells by insertional activation. This pattern of viral spread through one intermediate cell type to ultimately lead to disease in another cell type is a paradigm for complex viral pathologies, such as that exhibited by polioviruses.

The *sag* gene of MMTV was also recognized as acting as a host gene important in disease progression when a number of mouse genes, termed Mls for minor lymphocyte-stimulating antigen, were shown to map to endogenous MMTV proviruses, and ultimately were identified as the *sag* genes. The expression of Mls results in the clonal deletion of many T cells in mice carrying the gene. Thus, mice carrying endogenous proviruses will often lose T cells needed for virus replication, and will be resistant to exogenous MMTV disease.

A number of other viruses carry variants of the normal replication genes that cause specific pathologies in the infected host. One spleen focus-forming virus, SFFV-P, causes a severe polycythemia; infection leads to a massive expansion of erythroid precursors (BFU-E and CFU-E) and a concomitant loss of mature red cells. This agent consists of a complex of a replication-defective variant and a Friend MuLV helper virus to propagate it. The defective genomes carry a mutant *env* gene encoding a shorter SU molecule, termed gp55, that no longer functions to mediate virus entry. However, gp55 can bind directly to the erythropoietin receptor (EpoR) and stimulate the mitogenic and differentiative responses normally triggered by ligand binding to the receptor. This activity allows the virus to infect these dividing pre-erythroid cells; the continued expression of the envelope protein in these cells promotes their factor-independent growth and expansion in an autocrine loop. Ultimately a frank erythroleukemia results and may be associated with proviral activation of proto-oncogenes occurring as a result of the continuing infections. It is clear that the *env* gene of the virus is sufficient to cause the disease.⁶³⁹ A very similar virus, the SFFV-A, causes a severe splenomegaly and anemia. This virus is closely related to SFFV-P, and also activates the Epo receptor to expand immature cells. Variation in the envelope between these two strains alters the target cell and the consequences of its expansion.²⁷⁵ It should be noted that this mitogenic activity of gp55 is not a completely novel property of the deleted Env. The parental F-MuLV helper Env protein has a weak ability to bind and send mitogenic signals through the Epo receptor, presumably resulting in expansion of Epo receptor-positive cells. This increase in target cell number is presumably able to enhance virus spread, and thus serves as a positively selected trait for the virus. Other Env proteins, including those of the MCF viruses, may activate the IL-2 receptor.

Another replication-defective variant, the murine acquired immune deficiency syndrome (MAIDS) virus, causes a relatively acute hyperproliferation of B-lineage cells in infected mice.^{20,249} There is a subsequent proliferation of macrophages and CD4⁺ T cells. The expansion of these cells displaces many other cell types, including T cells, and the animals eventually show a significantly defective immune response. The mechanism of the immunodeficiency is not fully clear, and there is some indication that an antigen-driven stimulation leads to an anergic state. However the immunosuppression occurs, the disease is in reality a lymphoproliferative disorder, distinct from human AIDS in its pathology. The causative agent is again a replication-defective variant carried by a replication-competent helper virus. The defective genome encodes a mutant Gag precursor in which the central portion, including the p12 region, is replaced by a foreign Gag derived from endogenous retrovirus sequences. The altered Gag has been shown to interact with the c-Abl protein, a tyrosine kinase first identified as the transduced oncogene of the Abelson MuLV, expressed in that virus as a Gag-Abl fusion protein. Thus, the MAIDS virus seems to act by forming a noncovalent interaction with the c-Abl protein as an approximate mimic of the Gag-Abl protein formed by transduction on the Abelson virus.

An ovine disease has attracted attention as a potential model for human lung cancer. Sheep pulmonary adenomatosis (SPA) is a contagious bronchiolo-alveolar carcinoma of sheep associated with an exogenous type D/B retrovirus, Jaagsiekte sheep retrovirus (JSRV). Epithelial tumor cells are sites of large amounts of viral DNA.⁴⁴⁷

Two of the epsilonretroviruses, the piscine (fish) retroviruses, cause a dermal sarcoma that shows a remarkable seasonal appearance and regression. The mechanism of transformation of cells by the virus is not totally clear, but seems to reflect the activity of a cyclin D homolog encoded by the viral genome. This gene, the *orfA* gene, may induce inappropriate entry of the cells into cycle by activation of a cyclin-dependent kinase (cdk).

Host Determinants of Retroviral Disease

A number of genes have been identified that determine sensitivity or resistance to retroviral diseases. Some of these genes act at the level of virus replication, directly controlling the ability of the virus to spread. The Fv1 locus described in the previous section is a good example of a gene that acts in a cell-autonomous way to restrict the replication of various MuLVs.²⁶⁹

A large set of those genes that affect sensitivity to viral disease modify the availability of target cells for virus growth, or the immune response to virus infection, therefore indirectly control the levels of viremia. The *Fv2* gene is an example of such a gene.³³⁵ Virus-susceptibility (*Fv2^s*) is dominant over virus-resistance (*Fv2^r*) at this locus. The virus-susceptible allele encodes a truncated form of the stem-cell kinase receptor (Stk), which promotes virus-induced erythroleukemia⁴⁷⁰; expansion of the *Fv2^s*-expressing cells may provide increased cells for virus replication. The *Fv2^r* homozygous mice are resistant due to a limited expansion of BFU-E clones, and a reduced ability of the Friend MuLV to find sensitive targets.^{60,575} Finally, mutations in certain genes can sensitize or predispose organisms to oncogenic transformation by retroviruses. Because transformation is almost always a multistep process, mutations in one of the genes in a transforming pathway can increase the frequency with which a virus-mediated loss of another gene becomes manifest as a frank

tumor. Thus, knock-out mutations of such tumor suppressors as the *p53* or *p73* genes can sensitize to transformation by a number of oncogenic retroviruses. Similarly, a preexisting transgene such as a regulated version of the *myc* oncogene, *Em-Myc*, can predispose particular cells expressing the gene to insertional activation of other proto-oncogenes in viremic animals.⁶⁰⁶ New integration sites that would not normally be detected in wild-type mice are often utilized in such mice.

ACUTE TRANSFORMING RETROVIRUSES: TRANSDUCTION OF CELLULAR PROTO-ONCOGENES

Many potent transforming retroviruses, which can initiate rapid tumor formation with a quickly fatal outcome, have been isolated and characterized. These viruses are recombinant transducing viruses, which have acquired portions of cellular genes that are responsible for the transforming activity. The prototype of these viruses is the Rous sarcoma virus, which carries a transforming version of the *c-src* gene. In the exceptional case of RSV, the viral replication functions, including the coding regions for the Gag, Pol, and Env proteins, are all intact so that the resulting transducing genome is replication competent. In nearly all other cases, the acquisition of the transforming gene from the host has occurred with a loss of one or more of the viral replication functions, so that the resulting virus is replication defective. However, these genomes retain all the *cis*-acting elements needed for their replication, and thus can be transmitted from one cell to another by a replication-competent helper virus. The concerted replication of two viral genomes in a complex—a replication-competent helper virus and a replication-defective acute transforming virus—is a common feature of most of the transforming viruses.

Transforming viral genomes exhibit a range of different structures, but have some features in common. Those segments required in *cis* for viral replication are always retained: the LTRs, the PBS, and the PPT are present because they are required for reverse transcription and forward transcription. The RNA packaging signals are retained. Much of the regions required in *trans* are often deleted, since these functions can be provided by the helper, and are replaced with the host sequences. The host gene may be expressed separately, or, more often, is fused to Gag, Pol, or Env sequences to form a fusion protein.

The formation of a transducing virus is thought to involve a complex series of events that results in the acquisition of the coding regions of a host gene by the replication-competent parental virus.⁵⁷⁷ Several models have been proposed to account for the observed structures including DNA-based events (e.g.,⁵⁴⁰), but more often, RNA-based events (summarized in 594). The most commonly accepted model includes the following steps (Fig. 47.22):

- The process begins with the insertion of a provirus upstream of the gene to be transduced. An insertion in the middle of a gene can initiate the transduction of the downstream portion of that gene.
- Next, readthrough transcription beginning in the 5' LTR generates a large RNA containing viral sequences fused to downstream sequences. This event can be enhanced by lesions in the 3' LTR that prevent normal RNA processing

FIGURE 47.22. Two pathways for the acquisition of host oncogenes by replication-competent retroviruses in the formation of an acute transforming genome. Integration is shown establishing a provirus within a proto-oncogene in the same transcriptional orientation (*top*). Either of two processes then occurs. In one mechanism (*left*), a deletion of the chromosomal DNA fuses the 5' half of the provirus to the downstream portion of the gene. The fused DNA then encodes a fused RNA, which may be spliced and packaged into virion particles along with wild-type helper RNA. During reverse transcription, RT switches from the helper to the fusion RNA to append the 3' portion of the helper onto the hybrid RNA. The completed reverse transcribed DNA is integrated and transmitted thereafter as a replication-defective viral genome. In the other mechanism (*right*), a readthrough RNA extending from the 5' LTR through the provirus and into the downstream portion of the gene is formed. The RNA is packaged into virion particles along with wild-type helper RNA. During reverse transcription, RT switches from helper to host and back to helper RNAs to form the hybrid genome. As before, the completed reverse transcribed DNA is integrated and transmitted thereafter as a replication-defective viral genome. In either scenario, the transducing genome may undergo additional rearrangements and mutations under selective pressure for more efficient transforming activity and transmission.

and polyadenylation at this site. Alternatively, a deletion in the DNA could fuse the 5' half of the provirus to downstream sequences, again leading to the expression of a fusion RNA.

- In either mechanism, the chimeric RNA can be spliced and is then packaged into virions along with the RNA of a helper virus.^{236,578}

- Finally, nonhomologous recombination occurs during reverse transcription to append 3' viral sequences to the chimeric genome. A template switch by RT from the helper to the chimeric RNA during minus-strand synthesis can mediate such a nonhomologous event at low, but easily detected, frequencies.^{204,592,667} The completion of reverse transcription on this template would result in the generation of a provirus

with host sequences flanked by viral termini, similar to those seen in transforming retroviral genomes. Consistent with this model is the appearance of poly(A) sequences at the 3' junction between host and viral sequences in some viruses; if the translocation by RT from viral to host RNA occurs in the host poly(A) sequences, a portion will be retained in the final genome.

A key feature of the resulting genome is the presence of only the mRNA sequences—that is, only the exons and not the introns—of the host gene. Thus, very large genes can be transduced by retroviruses because they carry only the exonic coding regions of the gene. Most transforming retroviral genomes are not only a result of these relatively simple recombination events, but rather have also undergone multiple rearrangements thereafter. The RNAs encoded by these genomes often exhibit complex patterns of splicing, which can involve cryptic splice sites in both virus and host sequences. Several of the known rodent viruses carry segments of endogenous retroviral or virus-like sequences, especially the virus-like 30S (VL30) elements.

The genes that have been identified on the many acute transforming viruses are wildly diverse in their sequence and functions. These genes are among the most intensively studied of all known genes; their clear involvement in oncogenesis has focussed enormous attention on their structures and function. The genes include growth factors (v-Sis); growth factor receptors (v-erbB); intracellular tyrosine kinases (v-src, v-fps, v-fes, v-abl), members of the G protein family (H-ras, Ki-ras); transcription factors (v-myc, v-erbA); and many others. The genes are now recognized as playing major roles in mitogenic signaling pathways; in the control of the cell cycle; and in anti-apoptotic pathways that act to limit cell survival. There is no indication that all such genes have been identified, and it is likely that new transforming viruses will continue to provide new examples of genes that can be activated by transduction to initiate tumor formation.

The acquisition of these genes, as noted previously, is often associated with fusion of the coding region to Gag, Pol, or Env sequences. Thus, the expression of the oncogene results in a fusion protein that may exhibit dramatically altered biochemical activity, intracellular localization, or stability. These changes are often a key aspect of the activation of the normal function of the proto-oncogene to create the fully transforming viral oncogene. In other cases, or in addition to these alterations, there may be specific mutations that arise during or after the transduction process. These mutations, which may be as simple as a point mutation or as drastic as a frameshift or deletion mutation, can be the major cause of activation of the oncogene. Presumably, the high mutation rate of viral replication allows for the appearance of such mutations, and a selection for tumor formation in enhancing virus spread is responsible for the appearance of these mutations.

ENDOGENOUS VIRUSES AND VIRUS-LIKE SEQUENCES

Virtually all cells contain a large number of retroviral or retrovirus-like DNA elements integrated into the germ line (for comprehensive reviews, see 58,346,462,567). These endog-

enous retroviral elements can represent a substantial fraction of the total DNA in a genome; while the sequences most closely related to the exogenous retroviruses may only represent a percent or so of the total DNA in many species, the retroelements in total can occupy 10% or more of the genome.⁵⁹¹ These elements have presumably accumulated over evolutionary times, with no mechanism by which they can be removed and no strong selection against individuals that acquire them.

The retroviral provirus is closely related in structure and mode of replication to transposable elements—the retroelements—found in the genomes of all living things, from bacteria to humans.⁵⁷ Many of these elements are remarkably similar to proviruses, with LTRs that function similarly and with sequence similarity to *gag* and *pol* genes. The retroviruses have probably existed as parasites of cells from very ancient times, and evolved together with transposable elements.¹⁴⁰

Endogenous Elements in Chickens, Mice, Pigs, and Humans

Many endogenous retrovirus sequences have been characterized in chickens and other birds, and can be grouped into at least four families. The ALV-related elements were among the first to be discovered, including the replication-competent provirus RAV-0. Most of the other family members are replication defective and lack *env* sequences. The newer families of such viruses continue to be characterized.⁵⁵⁷

A vast literature describes the endogenous retrovirus sequences in inbred mice.^{39,112,255,304,568} At least eight families have been described, though only four have been studied in detail. The virus-like 30S (VL30) elements are present in the genome at a copy number of perhaps 100 to 200²; these elements encode a 30S RNA that is packaged efficiently into the virion particles of exogenous viruses and contaminates most virion RNAs. They presumably represent a parasitic RNA that spreads by exploiting exogenous viruses. The intracisternal A-type particle (IAP) elements are present at about 1,000 to 2,000 copies in the genome.^{349,423,432} These elements can express intracellular particles containing RT, but the particles are budded into the ER and not released from cells. Most lack *env* genes, and thus cannot form infectious particles. However, a few members do contain *env* sequences. Some IAPs can transpose intracellularly at low frequencies. Third, there are a small number of proviruses (0–4 per genome) closely related to MMTV that encode functional B-type viruses. Fourth, there are proviruses related to the exogenous MuLVs, present at 50 to 100 copies per genome.⁵⁶⁸ These proviruses are all very similar to one another, but can be categorized according to their similarity to exogenous viruses that utilize particular receptors into four groups: the ecotropic, xenotropic, polytropic, and modified polytropic. The distribution of these sequences among different murine species and subspecies can help reveal their evolution and spread. For example, xenotropic MLV-related proviruses are present only in *Mus musculus* subspecies, while polytropic MLV-related proviruses are found in both *M. musculus* and *M. spretus*. Replication-competent members of the family are found in many, but not all inbred mice.¹⁰⁶ (For reviews of the properties of the murine endogenous retrovirus genomes, see 180,262).

The potential to use pig organs or cells in xenotransplantation into humans has raised considerable interest in the presence of endogenous retroviral elements in the pig. Although

viruses can be rescued from porcine cells, and while these viruses can infect human cells very efficiently,^{461,635} preliminary studies suggest that they are not easily transmitted to humans in transplant settings. There remains a real possibility for their transfer to humans, however, and the consequences could be significant.

Retroviral elements are also abundant in the human genome.^{56,346,369,370} These elements are collectively termed HERVs, for human endogenous retroviruses, and subgroups are denoted by a letter indicating the amino acid specificity of the tRNA primer. Most are defective, but a very small number of these elements are still actively transcribed in somatic cells and are capable of transposition to new sites. The distribution of the HERV-K family in various primates has been surveyed to help build evolutionary trees of these species.²⁶⁸ There are also provirus families distantly related to the lentiviruses; some have the potential to encode rev-like elements that could, in principle, be pathogenic.

Properties of the Endogenous Provirus-Like Elements

The distribution of elements in a given species is relatively stable over the course of a few generations. Thus, most individuals in an inbred population show a constant, characteristic pattern of endogenous elements. The rate of loss of a given provirus is very low, and the appearance of new proviruses is rare in most animals. However, the pattern is very different in different species, and even in different strains of animals, suggesting that rearrangements happen often over longer evolutionary periods. It is known that new copies can appear at higher frequency if newborn females are viremic. Thus, early infection of germ cells can introduce new proviruses into the germ line. This route can even be used to create mutations *de novo* in laboratory mice at reasonable frequencies.

Most endogenous proviruses are transcriptionally silent; the DNA is often heavily methylated and so repressed. These may reflect the mechanisms by which the transcription of many exogenous viruses are repressed *in vivo*. Expression of many of the endogenous viral RNAs is induced by agents causing DNA damage, such as UV light and BrdU; the expression of others is stimulated by glucocorticoids. The IAPs are often induced during the differentiation of various cell types, and even more often in immortalized tumor cell lines.

The bulk of the endogenous retroviruses are fossil DNAs, grossly defective, and no longer capable of encoding proteins; the ORFs contain numerous stop codons and frameshifts that would preclude the formation of any functional viral gene products. However, these elements can often give rise to RNAs, which can be packaged efficiently by virions encoded by exogenous viruses and give rise to new proviruses. Furthermore, these co-packaged RNAs can then recombine with the exogenous viral RNAs and contribute small sequence blocks to these viruses, potentially altering the host range and replication properties of the virus. The continuous contribution of endogenous sequences to virus evolution is a fact that needs to be considered whenever genetic selections are imposed on a virus. In addition, a few of the elements are functional, and can transpos intracellularly or can even give rise to replication-competent viruses. Even when viruses are induced from the elements, however, the viruses are most often not highly pathogenic for the host in which they reside. Thus, many of the inducible ele-

ments in the mouse are xenotropic, and cannot spread in the animal; those that can do not cause an acute disease. The LTRs of the endogenous elements are often quite weak as transcriptional promoters as compared to those of exogenous viruses. This may reflect selections against highly pathogenic agents either before or after their introduction into the germ line.

The creation of a new provirus in the germ line by necessity creates a mutation, and while most such insertions probably have no significant effect, occasionally deleterious germ-line mutations occur. A number of ancient, "spontaneous" mutations upon analysis have been found to have been caused by a proviral insertion. These include such classic mutations as the rd1 allele, causing a slow retinal degeneration, and which includes an insertion affecting the beta subunit of the retinal cGMP phosphodiesterase; the hr mutation, causing a hairless phenotype; the dilute coat-color allele d; and a mutation termed Slp (for sex-limited protein) in the C4 complement gene, in which an insertion of a viral LTR renders the gene androgen responsive.

Many of the endogenous elements may be positively selected in their host species. This may be due to advantageous mutations that are created by the insertion, or to antiviral effects mediated by the gene products encoded by the endogenous proviruses. The *Fv1* and *Fv4* genes are examples of such elements. These virus-like elements confer resistance to exogenous viruses, and may serve to protect the host from leukemia induced by infection. The MMTV *sag* gene, if present on an endogenous provirus, acts to delete T cells that would respond to the superantigen; thus, subsequent infection by an exogenous MMTV cannot use *sag* to induce a proliferation of cells needed for its vigorous replication. The inherited provirus therefore protects the host from MMTV disease.

RETROVIRAL VECTORS, PACKAGING LINES, AND GENE THERAPY

The structure and mechanism of transmission of the naturally arising replication-defective transforming viral genomes provide a clear model for the directed use of retroviruses to mediate gene transfer. Retroviral vectors that mimic the structure of the transforming viruses can readily be generated, and can be engineered to carry the cDNA sequences of virtually any gene. These genomes can then be propagated with wild-type virus as helper. However, it is also possible to generate helper-free preparations of particles that transduce the vector genome via the early steps of the life cycle without delivering the helper genome, preventing subsequent spread of the vector. These helper-free particles are generated in packaging cell lines: cells engineered to express the *gag*, *pol*, and *env* genes but not expressing packageable helper viral RNAs. The first such lines simply carried a provirus lacking the Psi site, the RNA packaging signal.³⁶⁸ These cells produce virions deficient in the helper genome, and introducing a Psi+ vector construct into these cells results in the encapsidation and release of the vector RNA into those particles. These particles can then be harvested and used to deliver the vector and its gene into susceptible cells. It is also possible to generate transducing virus preparations by transiently transfecting cells with DNAs that encode the helper functions and DNAs that encode the vector. This approach is preferable in instances in which the viral

gene products are toxic and therefore difficult to express stably in a packaging cell line.

A limitation of these packaging systems is that small amounts of the Psi-minus helper RNA are encapsidated along with the vector. Endogenous retroviral genomes, such as the virus-like 30S RNAs (VL30),² are also encapsidated efficiently, and recombination events between these RNAs during reverse transcription can recreate a replication-competent virus. These events are probably similar to recombinational repair of mutations in genomes that occur during growth in cell culture. This issue has raised considerable fears that gene therapy vectors intended for therapeutic use could initiate a viremia, and perhaps a viral leukemia, in patients. More elaborate cell lines, in which the *gag*, *pol*, or *env* genes are expressed via separate RNAs, can reduce the frequency with which such recombination events occur to very low levels.

Retrovirus particles transducing a desirable gene can be directed to target cells through the use of many distinct envelope proteins. This method is possible because retrovirus particles can readily form pseudotypes; that is, they can incorporate and use the envelope proteins of a wide array of different viruses. The wide range of pseudotypes that can be formed presumably reflects the flexibility of the core-envelope interaction. The host range can be further expanded or restricted by the engineering of envelopes with new binding specificities. Chimeric envelope molecules have been particularly popular tools in targeting virions to new receptors. Another approach is to engineer animals that express a foreign receptor in a tissue-specific manner, and deliver genes with a virus envelope that only recognizes the transgenic receptor.¹⁶⁸ The envelope-receptor interaction can even be reversed: it is possible to express a particular virus receptor molecule on the virion surface, targeting the virus to those cells expressing the corresponding viral envelope.²⁴

A major limitation of early retroviral gene therapy efforts is the inability of most helper viruses to mediate the infection and transduction of nondividing cells. The major block is during the early stages of infection, when there is a strong requirement for cell division for infection by most viruses.⁵¹⁷ However, the lentiviruses have the ability to infect nondividing cells, and thus gene therapy based on lentiviral packaging systems could overcome this limitation (for review, see 9). Efforts have fully substantiated these expectations: delivery to nondividing neurons and to poorly dividing primary lymphocyte cultures has been demonstrated with vectors based on HIV-1^{55,276,408,409} as well as FIV.⁴⁸⁰

PERSPECTIVES

The study of retroviruses has led to a detailed characterization of many steps of virus replication as well as to important fundamental discoveries concerning host physiology and genetics. The viruses have served as entrées into such phenomena as cell surface receptors, cell division, DNA synthesis, the cell cycle, mechanisms of gene expression, and intracellular transport. The value of focusing on retrovirus functions in unraveling cellular functions is clear: these agents have evolved over huge periods of time to exploit key aspects of the cell, and we should make use of their success to help identify those aspects. There is every reason to believe that their continued study will reveal even more new aspects of cell physiology.

Perspectives

been described in Japan. ATL is characterized by several clinical features, including skin lesions, hypercalcemia, the presence of leukemic cells with multilobulated nuclei, and an aggressive clinical course.^{354,376} Patients with ATL were clustered in a limited area of Japan, including the islands of Kyushu and Okinawa, which suggested a pathogen(s) as a causative agent. In 1981, it was reported that ATL patients had antibodies that reacted with ATL cell lines,¹³¹ suggesting that ATL was caused by an unknown virus. Thereafter, it became evident that the sequence of the provirus in ATL cells was almost identical to that of HTLV. The clinical features of ATL resemble those of mycosis fungoides. Therefore, the patient from whom the HTLV-infected cell line was established might have been misdiagnosed. The diagnosis should have been ATL.

In 1984, HTLV-1 was reported to be associated with tropical spastic paraparesis (TSP),⁹³ and the same disease was reported in Japan as HTLV-1–associated myelopathy (HAM).²⁸¹ Both diseases were subsequently classified as the same disease and are referred to as HAM/TSP. Other inflammatory diseases were found to be linked to this virus, including HTLV-1–associated uveitis, myositis, alveolitis, and infective dermatitis.^{116,204,242,243,258,341}

HTLV-2 was discovered in a cell line that was established from a patient with T-cell variant hairy cell leukemia.³¹¹ Thereafter, infection with this virus was found in the native Amerindian population of North, Central, and South America, in people in Central and West Africa, and in drug abusers in the United States and Europe.⁷⁵ HTLV-2 has been reported to cause a neurodegenerative disease resembling HAM/TSP.¹⁴⁰ However, no definite associations with lymphoproliferative diseases have been reported.

In addition to HTLV-1 and -2, HTLV-3 and -4 were isolated from bushman hunters in Cameroon.⁴⁰⁰ There are limited numbers of individuals infected with HTLV-3 and -4; thus, their pathologic roles in human diseases are unclear.

INFECTIOUS AGENT

HTLV is a delta-type retrovirus, and an HTLV virion contains two copies of single-stranded genomic RNA. Upon viral entry into a host cell, the viral RNA is reverse transcribed (the transfer RNA for proline being utilized as a primer), and the viral genome becomes integrated into the host cellular DNA as a provirus. This genome encodes the structural (Gag, Env), enzymatic (protease, reverse transcriptase, integrase), nonstructural regulatory (Tax, Rex), and accessory proteins (p12, p30, p13, HBZ).

HISTORY

The discovery of oncogenic retroviruses in animals led to a search for retroviruses in human cancer cells. In 1980, the first human retrovirus was found in a T-cell line established from a patient with mycosis fungoides, and the retrovirus was named human T-cell leukemia virus (HTLV).^{85,296} Prior to this discovery, the disease entity of adult T-cell leukemia (ATL) had

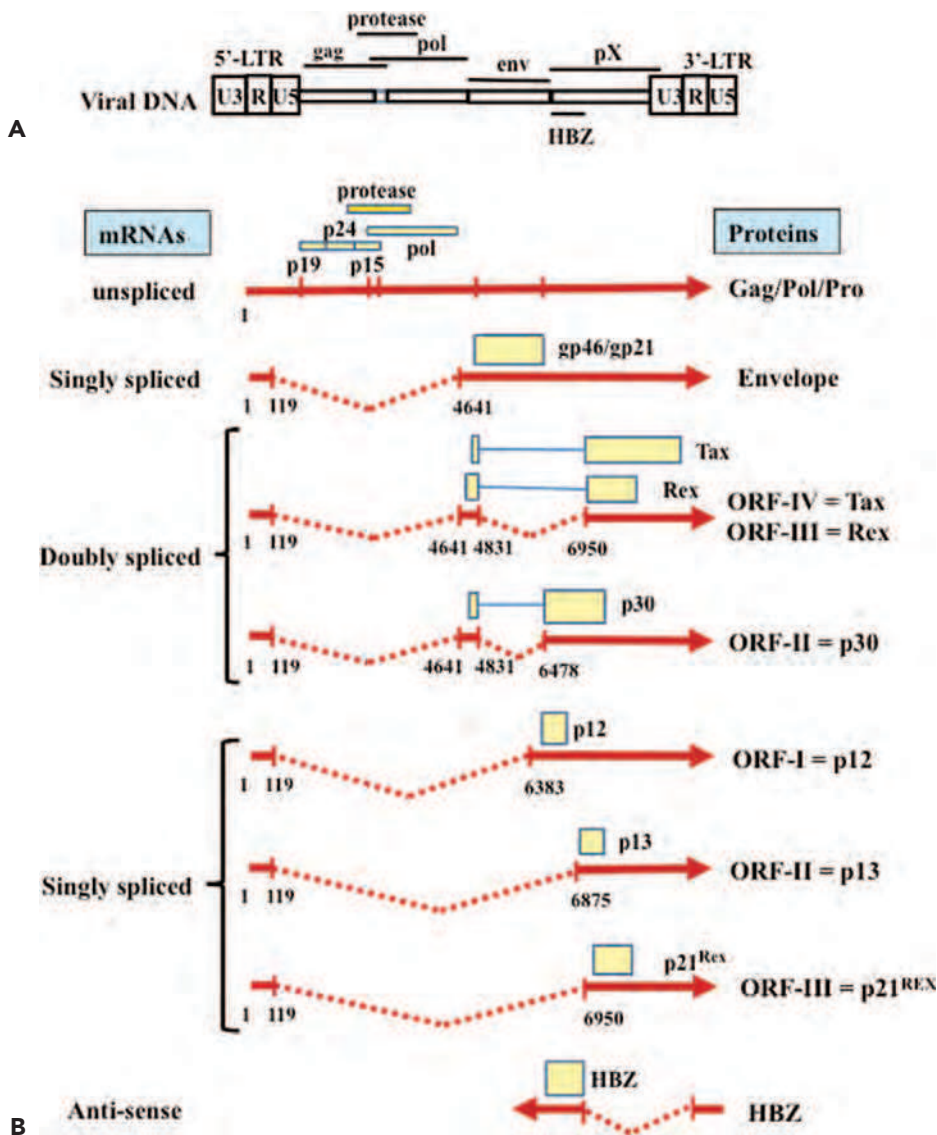

FIGURE 48.1. HTLV-1 genome organization, transcripts, and products.
A: Schematic organization of HTLV-1 proviral DNA. **B:** Structure, splicing, and orientation of HTLV-1 transcripts and their corresponding products.

Of these proteins, only HBZ is encoded by the minus strand of the HTLV-1 provirus.

HTLV-1 Gene Regulation

Overall HTLV-1 Messenger RNA Regulation

In addition to genomic unspliced messenger RNA (mRNA), HTLV-1 expresses multiple other mRNAs with distinctive splicings^{314,315} (Figs. 48.1 and 48.2). After infection of host cells, the initial dominant mRNA is the default doubly spliced *tax/rex* mRNA encoding the x-III and the x-IV open reading frame (ORF). Because the protein product Tax is a transcriptional activator of HTLV-1 transcription, Tax further amplifies the HTLV-1 transcripts, especially *tax/rex* mRNA, and their protein products. Once the other product, Rex, accumulates in a sufficient amount, it inhibits the nuclear export of *tax/rex* mRNA, instead increasing the export of singly spliced *env* mRNA and unspliced genomic RNA encoding *gag/pro-pol* (see Fig. 48.2), resulting in HTLV-1 release. Thus, Tax and Rex are essential for efficient HTLV-1 replication and production.

Tax-Dependent Transcriptional Activation

Tax is a protein of 353 amino acids, localized in both the nucleus and cytoplasm.¹⁰¹ Tax activates HTLV-1 transcription through the long terminal repeat (LTR)^{74,269,317,318,339} (see Fig. 48.2). The HTLV-1 LTR is divided into three regions: U3, R, and U5. Three repetitive 21-bp sequences in the U3 region act as Tax-responsive enhancers (TREs).³²³ Each 21-bp TRE is in turn composed of three elements—the core element and the elements 5' and the 3' to the core element—all of which are indispensable for Tax activation of HTLV-1 transcription. The core sequence of a TRE is highly similar to a cyclic adenosine monophosphate (cAMP) response element (CRE) and indeed acts as a binding site for the CRE binding protein (CREB)/activating transcription factor (ATF) family of transcription factors (CREB/ATF).^{29,421,429,430} Thus, a TRE is also referred to as a viral cAMP response element (vCRE) and is responsive to cAMP. The 5' and 3' elements within a TRE are GC-rich. Although Tax does not interact with TRE DNA by itself, it can do so when it interacts with DNA-bound CREB.^{429,430} When this happens, DNA-bound Tax interacts

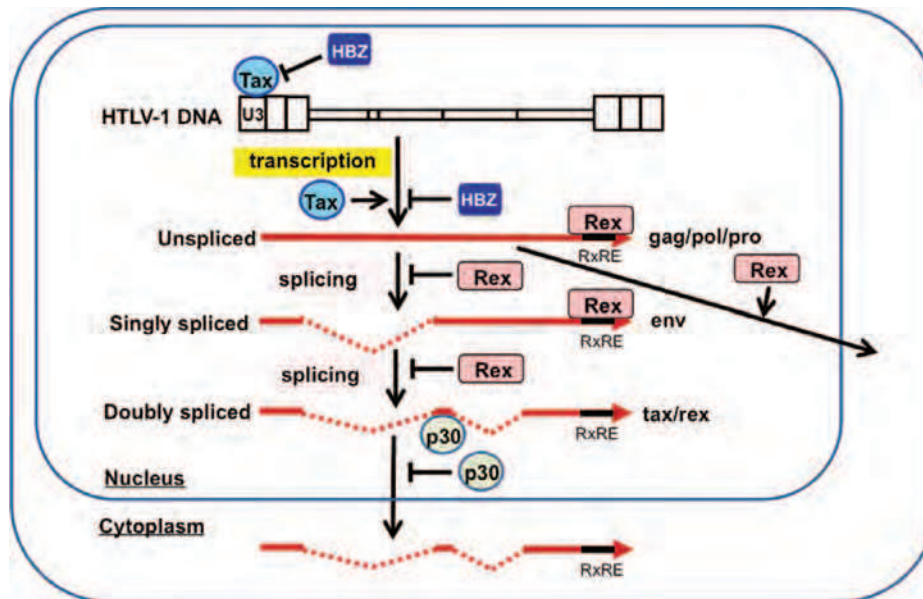

FIGURE 48.2. Overview flow chart of HTLV-1 gene regulation. HTLV-1 encodes three major transcripts: an unspliced genomic one, a singly spliced one, and a doubly spliced one, and these encode the Gag/Pro/Pol, Env, and Tax/Rex proteins, respectively. After initial infection, HTLV-1 dominantly expresses the default doubly spliced *tax/rex* transcript. Tax further augments viral transcription through the HTLV-1 long terminal repeat (LTR) promoter, and this activity is negatively regulated by HBZ. Upon accumulation of Rex, Rex inhibits the splicing of transcripts, thereby increasing the amounts of unspliced and singly spliced transcripts and their products (Gag, Pro, Pol, Env), resulting in HTLV-1 production. p30 inhibits the nuclear export of *tax/rex* transcripts to repress HTLV-1 gene expression. RxRE, Rex responsive element.

with the minor groove of the adjacent GC-rich sequences to stabilize the protein-DNA complex.^{214,215}

CREB is ubiquitously expressed and regulates several cellular genes, especially cAMP-induced genes.³⁹⁸ A cAMP-initiated signal phosphorylates CREB at serine 133, recruiting two transcriptional co-activators, CREB binding protein (CBP) and p300. An *in vitro* chromatin-based transcription study indicated that phosphorylation of CREB is essential for Tax activity through stabilizing the Tax/CREB/CBP/DNA complex. Moreover, Tax by itself induces the phosphorylation of CREB.¹⁹¹ Consistent with this observation is the fact that a drug that increases the intracellular cAMP level, and thus the phosphorylation of CREB, augments the Tax activation of HTLV-1 transcription.

CBP/p300 is a histone acetyltransferase that acetylates histone tails, thereby changing chromatin structures to activate transcription. *In vitro* and *in vivo* studies showed that p300 is crucial for Tax-dependent transcriptional activation, where p300, interacting with Tax and CREB, induces the acetylation of nucleosome histones over the TRE DNA.^{90,91,99,121,122,202,212,215,269} Interestingly, p300 recruitment by Tax to an integrated HTLV-1 promoter reduces the amount of histone H1 and H3 proteins on the promoter DNA, and stimulates the recruitment of RNA polymerase II.²¹¹ These results suggest that recruitment of CBP/p300 to the integrated promoter acetylates histone tails, thereby removing histone octamers from the HTLV-1 promoter. Histone chaperon NAP1 is a factor promoting Tax/CBP/p300-mediated histone eviction.³¹⁹

p300/CBP-associated factor (PCAF) is a co-activator for various cellular transcription factors, and it also augments Tax-induced transcriptional activation through the HTLV-1 promoter.¹⁶⁶ Like CBP/p300, PCAF is a histone acetyltransferase;

however, its activity is dispensable for co-activation of Tax. The well-known Tax mutant M47 (L319R, L320S), which is inactive for transcriptional activation of the HTLV-1 promoter but active for that of NF- κ B pathway, is defective in interacting with PCAF (Fig. 48.3).^{166,338}

Treatment of HTLV-1-infected T-cell lines with a histone deacetylase (HDAC) inhibitor (trichostatin A [TSA]) augments the expression of *tax/rex* mRNA as well as Tax protein, suggesting that HDAC(s) may inhibit HTLV-1 transcription in HTLV-1-infected cells.²²¹ Consistent with this hypothesis, HDAC1 and HDAC3 were found to inhibit Tax-induced transcriptional activation, and this inhibition was rescued by TSA treatment or expression of CBP.^{70,388} HDAC1 and HDAC3 were shown to interact with Tax, and chromatin immunoprecipitation analysis showed that HDAC1 was associated with integrated HTLV-1 promoter DNA. The amount of promoter-associated HDAC1 was reduced by expression of Tax, indicating that Tax, through interacting with HDAC1, dissociates HDAC1 from the integrated HTLV-1 promoter DNA.

TORCs and P-TEFb (CDK-9/cyclin T1) are additional positive regulators for Tax-dependent HTLV-1 promoter activation.^{53,54,167,197,336,434} Both proteins interact with Tax, and the knockdown of either by small interfering RNA (siRNA) reduces Tax-dependent activation. On the other hand, Bcl-3, by interacting with TORC3, acts as a negative transcriptional regulator of the HTLV-1 LTR.¹³⁷

Posttranscriptional Regulation of Viral RNA by Rex

HTLV-1 has two posttranscriptional regulators: Rex and p30.^{181,423} The roles of Rex and p30 in posttranscriptional mRNA regulations are described later.

FIGURE 48.3. Functional domains of Tax. Regions of Tax required for activation of the cyclic adenosine monophosphate response element binding protein/activating transcription factor (CREB/ATF) pathway, activation of the NF- κ B pathway, and transcriptional activation function of Tax measured by a Tax fusion protein with the yeast DNA binding protein GAL4 are indicated. Positions of substitution mutations in the Tax mutants M22 and M47 are also indicated. M22 is active for the CREB pathway but inactive for the NF- κ B pathway, whereas M47 is the reverse. LZ-2 and PDZ motifs distinguish Tax1 from Tax2. NLS, nuclear localization signal; NES, cryptic nuclear export signal; Zn, zinc finger motif; LZ-1 and LZ-2, leucine zipper-like structures.

In addition to unspliced genomic mRNA encoding *gag/pro-pol*, HTLV-1 produces singly spliced *env* mRNA and doubly spliced *tax/rex* and *p30* mRNAs. RNAs with introns generally undergo splicing by the cellular RNA machinery; otherwise, they are degraded. Thus, upon initial infection of host cells, HTLV-1 dominantly expresses doubly spliced *tax/rex* and *p30* mRNA. Once the Rex protein accumulates, Rex controls the ratio of spliced forms of HTLV-1 mRNAs^{125,150} (see Fig. 48.2). Rex increases the amount of singly spliced (*env*) and unspliced (*gag/pro-pol*) mRNAs, and reduces the amount of its own doubly spliced mRNA. Rex does this by inhibiting the splicing of singly spliced (*env*) and unspliced (*gag/pro-pol*) mRNAs, stabilizing them, and promoting their transport to the cytoplasm. In the absence of Rex, unspliced HTLV-1 mRNAs are retained in the nucleus owing to two *cis*-acting repressive sequences (CRS) in the 5' and 3' LTR;^{193,316} however, Rex overcomes the inhibitory activity of the CRS and induces the translocation of the unspliced RNAs into the cytoplasm.

These Rex functions are achieved through at least three activities. The first one is sequence-specific RNA binding. Rex interacts specifically with the HTLV-1 RNA at the Rex-responsive element (RxRE) located in the U3 and R regions of the 3' LTR.^{3,40,378} RNA binding by Rex is accomplished by an arginine-rich highly basic region in Rex (aa1–19).¹¹⁴ This domain also contains a nuclear localization signal (NLS) and a nucleolus targeting signal, which allow Rex to enter the nucleolus where it can interact with the RNA.^{268,335} The RxRE RNA forms a long stem-loop structure, and one stem loop (called *stem-loop D*) is essential for Rex binding and the function.¹⁰⁶ The second Rex function (multimerization) is mediated through aa32–133.³⁹⁶ Rex mutants that cannot form multimers behave as dominant-negative proteins.^{38,395} The third Rex function is interaction with the nuclear export receptor CRM1/exportin 1, which mediates the transport of viral mRNAs from the nucleus to the cytoplasm. Interaction with CRM1 is also required for multimerization of Rex, because a Rex mutant defective for CRM1 interaction failed to form a multimer. Rex contains a typical leucine-rich nuclear export signal (NES) (aa81–94) that mediates its interaction with CRM1. HTLV-1

production is less efficient in rat cells than human cells because Rex is less active in rat cells than human cells. The rat CRM1 is impaired in promoting Rex to form multimers, which may explain the reduced activity of Rex in rat cells.^{111,426}

Rex is activated by phosphorylation.¹⁸⁷ Whereas phorbol myristate acetate (PMA), an activator of protein kinase C (PKC), transiently enhances phosphorylation of Rex, treatment of HTLV-1-infected cell lines with a PKC inhibitor reduces the amount of unspliced *gag-pol* mRNA.² Liquid chromatography tandem mass spectrometry analysis showed that Rex is phosphorylated at multiple sites, and mutation analysis indicated that phosphorylations at Ser-97 and Thr-174 are critical for its function.¹⁸⁷

Several other host factors can also positively or negatively regulate Rex activity. They include hnRNPA1, B-23, RanBP3, RIP/Rab, and eIF5A.^{1,39,110,182} hnRNPA1 binds to RxRE RNA, inhibiting the binding of Rex and thereby preventing Rex activation of the RxRE reporter.⁶⁵

Posttranscriptional Regulation of Viral RNA by p30

p30 is encoded by the doubly spliced mRNA of x-II ORF and is a protein of 241 amino acids.^{21,27} It is unusually rich in Ser (23%) and Arg (12%), and highly basic with theoretical isoelectric point of 11.71. p30 is localized in the nucleus and the nucleolus,^{26,97,98} and it interacts with the ribosomal protein RPL18a.⁹⁸

p30 inhibits the nuclear export of doubly spliced *tax/rex* mRNA through retaining the mRNA in the nucleus.²⁶² p30 binds to the splice junction region (*env* exon) of *tax/rex* mRNA. p30 has four NLS and is retained in the nucleus.⁹⁸ In addition, a fraction of p30 is localized in the nucleolus, although this localization is not essential for its activity. Studies of p30-green fluorescent protein fusion proteins identified two nucleolar retention signals, each consisting of a short Arg-rich stretch. Although p30 has a peptide with homology to an NES, heterokaryon assays indicate that p30 is not a shuttling protein.

Interplay Between Rex and p30

Although both Rex and p30 interact with HTLV-1 RNA and decrease the amount of *tax/rex* mRNA exported from the

nucleus, they generally have opposite functions in virus production. Whereas Rex stimulates virus production through augmenting the expression of structural proteins (Gag, Pol, Env), p30 has no direct effect on virus production and in fact inhibits it through reducing the expression of Tax and Rex. Interestingly, the Rex and p30 proteins interact with each other, and their interaction is augmented by the presence of the viral mRNAs.³³³ p30 has little effect on Rex activity; thus, Rex counteracts p30 activity and induces the expression of Tax/Rex proteins. Therefore, the ratio of these two proteins may be a factor controlling the transition between virus latency and virus production.

Interplay of p30 with HBZ

HBZ is another virally encoded gene (discussed later). Ectopic expression of HBZ RNA increases the expression of *tax* mRNA and Tax protein from HTLV-1–infected cells. Moreover, HBZ blocks the p30-mediated inhibition of Tax protein expression from *tax/rex* mRNA.⁵⁵ This is likely owing to an antisense mechanism, because p30 transcripts originate from a region overlapping with HBZ but in the opposite orientation.

Transcriptional and Posttranscriptional Regulation of Cellular Genes by p30

p30 can play roles in the HTLV-1 life cycle by regulating cellular genes.^{235,366,424,425} Microarray analysis using total and cytoplasmic mRNA of peripheral blood mononuclear cells (PBMCs) indicated that p30 up-regulates 15 cellular genes and down-regulates 65 at the transcriptional level. In addition, nuclear export assays indicated that p30 up-regulates 33 mRNAs and down-regulates 90 at a posttranscriptional level.³⁶⁶ Human T cells immortalized by a p30-defective HTLV-1 mutant were more sensitive to camptothecin (an anticancer drug)-induced apoptosis than those immortalized by wild-type virus, suggesting that p30 may influence sensitivity to apoptosis. In addition, p30 interacts with CBP/p300 and Tax.^{424,425} Through this interaction, p30 inhibits Tax as well as CREB-mediated transcriptional activation of the HTLV-1 LTR.

Phenotypes of Rex and p30 Knockout HTLV-1

Knockout studies indicate that Rex is essential for persistent HTLV-1 infection in rabbits but not required for immortalization of human T cells *in vitro*.⁴¹⁷ The defect in infection can be explained by the mRNA export regulatory function of Rex described earlier: Infection cannot be established if virus production is insufficient. On the other hand, studies of a p30-defective HTLV-1 (a stop codon at amino acid position 3 of p30 with an HBZ mutation of Ser-153 to Tyr) suggested that p30 is dispensable for both infectious virus production and immortalization of primary human T cells *in vitro* and persistent infection in rabbits.³³² Nevertheless, it is essential for efficient viral propagation in macaques.³⁸¹ Twelve weeks after infection of macaques, all of the p30-defective HTLV-1 had reverted to wild-type virus, indicating that p30 was crucial for maintaining HTLV-1 persistent infection. Interestingly, whereas this p30-knockout HTLV-1 produced the viral antigen equivalently to wild-type virus in a B-cell line, it does poorly in human dendritic cells (DCs),³⁸¹ suggesting that HTLV-1 infection of DCs is involved in persistent HTLV-1 infection in macaques and that p30 is necessary for this function. HTLV-1–infected DCs can transfer HTLV-1 to CD4+

T cells, and this transfer may play a crucial role in the maintenance of persistent HTLV-1 infection.

Latent HTLV-1 Infection *In Vivo*

Whereas HTLV-1–transformed T-cell lines *in vitro* express abundant amounts of HTLV-1 mRNA and proteins, fresh PBMCs of HTLV-1–infected individuals generally express only a polymerase chain reaction (PCR)-detectable level of viral mRNA and an undetectable level of viral proteins, indicating that HTLV-1 expression is suppressed in these cells. However, once such HTLV-1–infected PBMCs are cultured *in vitro*, gene expression is initiated within a few hours.

Reactivation of HTLV-1 Transcription

It should be noted that infected individuals have high titers of antibodies against HTLV-1 and high anti-HTLV-1 cytotoxic T-lymphocyte (CTL) activity. Thus, HTLV-1 replication must occur either transiently but repeatedly or constitutively in specific cells other than peripheral blood lymphocytes, which are latently infected. Indeed, there are several circumstances in which HTLV-1 is reactivated to produce viruses. First, several stress agents induce expression of HTLV-1. For instance, arsenic trioxide, an oxidative stress response inducer, enhanced virus production.¹¹ In addition, deprivation of interleukin 2 (IL-2) from IL-2–dependent HTLV-1-immortalized T cells induced expression of the HTLV-1 gag protein.³⁹¹ This result suggests that the levels of IL-2 may regulate HTLV-1 gene expression *in vivo*.

Tax

In addition to activation of viral transcription, Tax plays pivotal roles in HTLV-1 immortalization of T cells, persistent infection, inflammation, and pathogenesis. Such pleiotropic Tax functions are introduced in the following sections.

Tax Plays Crucial Roles in HTLV-1 Immortalization and Persistent Infection

Co-culture of lethally irradiated HTLV-1–infected T cells with PBMCs or cord blood mononuclear cells (CBMCs) in the presence of IL-2 for approximately 10 weeks establishes immortalized HTLV-1–infected T-cell lines (called *HTLV-1-immortalized cells*), and long-term culture of such cells occasionally confers IL-2–independent growth to some cells (called *HTLV-1-transformed cells*).^{241,409} It should be noted that such HTLV-1-immortalized/transformed cells do not produce IL-2. These results suggest that in infected individuals, HTLV-1 establishes lifelong persistent infection by immortalizing/transforming T cells, and these cells grow in an IL-2–dependent and/or an IL-2–independent manner.

Tax is indispensable for immortalization/transformation of human T cells as well as for persistent HTLV-1 infection in a host, because deletion or mutation of the *tax* gene in recombinant HTLV-1 abrogates immortalization as well as persistent infection in rabbits.³⁰⁰ Moreover, Tax by itself, without other viral products, immortalizes primary human and rat T cells in the presence of IL-2 *in vitro*.^{4,104,251} However, transduction of Tax alone into PBMC does not lead to IL-2–independent transformation of T cells, suggesting that HTLV-1 has another factor required for IL-2–independent transformation. The functions of Tax associated with immortalization of T cells and HTLV-1 pathogenesis is introduced in the following section.

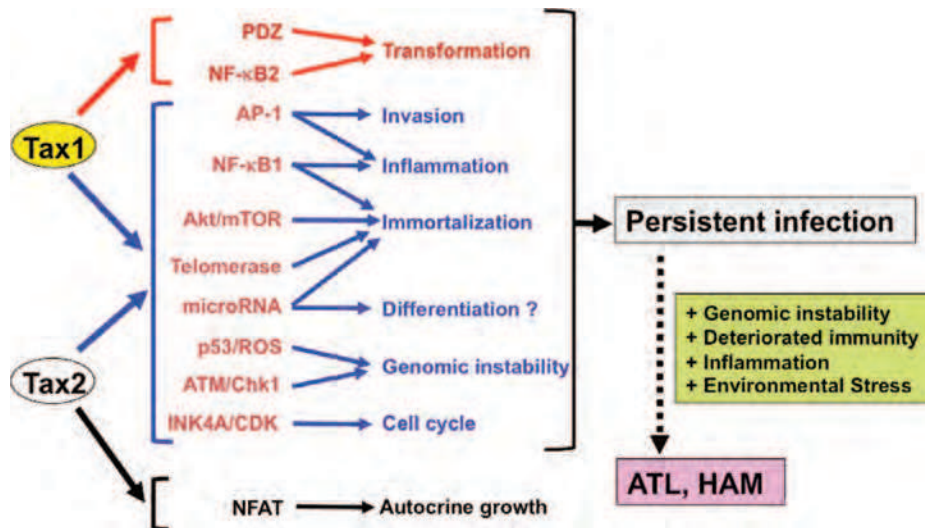

FIGURE 48.4. Functional similarities and differences between Tax1 and Tax2. The functions of Tax1 and Tax2 are classified into three groups: Tax1 specific (red), Tax2 specific (black), and common to both (blue).

ACTIVATION OF NF-κB BY TAX

Tax activates the transcription factor NF-κB, thereby inducing the expression of several cellular genes (Fig. 48.4), and this activity is crucial for multiple aspects of the HTLV-1 life cycle.^{22,41,168,216,231,301,328,342} For instance, recombinant HTLV-1 carrying a mutant Tax that cannot activate NF-κB fails to immortalize human T cells *in vitro*.³⁰⁰ Moreover, several NF-κB inhibitors induce prominent apoptosis in HTLV-1-infected T cells, indicating that NF-κB is crucial for survival of HTLV-1-infected T cells.

NF-κB is a family of transcription factors including NF-κB1 (p50), p65, c-Rel, NF-κB2 (p52), RelB, and Bcl-3, and these factors are divided into two groups belonging to the canonical (NF-κB1/p50, p65, c-Rel) and the noncanonical (NF-κB2/p52, RelB, Bcl-3) pathways. These two NF-κB pathways are both activated by Tax (see later) in T cells.⁴⁰³

To activate the canonical pathway, Tax interacts with several NF-κB regulators. IKKγ is essential for Tax activation of NF-κB, because the mutation of IKKγ in fibroblasts or T cells totally abrogates Tax activation of NF-κB.^{56,57,89,120,411} IKKγ is a scaffold component of the IκB kinase (IKK) complex, IKKα/IKKβ/IKKγ. Through interacting with IKKγ, Tax activates IKKβ to induce phosphorylation and degradation of IκBs (IκBα, IκBβ), thereby allowing nuclear translocation of p50/p65.^{56,89,102,223,344} In addition, Tax activates IKKα to phosphorylate p65 (at Ser-536), which stimulates its transcriptional activation function.²⁷⁰

Whereas NF-κB in primary T cells is activated transiently by various immune signals such as antigenic stimulation, it is constitutively active in HTLV-1-infected or Tax-expressing cells. Transient activation of NF-κB in normal cells is regulated by several negative feedback regulators. Tax interacts with one such negative regulator, Tax1BP1, via the adaptor optineurin,^{270,320} inducing constitutive NF-κB activation by Tax.

CBP/p300 appears to play a role in not only the CREB/ATF pathway but also in the NF-κB pathway. Tax and NF-κB/p65 form a ternary complex with CBP in the nucleus of HTLV-1-infected T cells, and this complex is associated with activation of the NF-κB pathway.³⁵⁰ In addition to p65, Tax has been shown to interact with other NF-κB subunits (p50, p52, c-Rel) as well as its inhibitors (IκBα, p105), although the

precise roles of these interactions in NF-κB activation by Tax have not yet been established.^{132,133,249,345} Tax also interacts with MEKK1, TAK1, TAK1-binding protein 2, and protein phosphatase 2A, which are also associated with activation of NF-κB by Tax.^{19,78,141,402,419}

Tax also activates the noncanonical NF-κB pathway.⁴⁰³ Tax1 simultaneously binds to the IKK complex (IKKγ, IKKα) and NF-κB2/p100, but not IKKβ, and thus induces IKKα-mediated phosphorylation of p100, its processing into p52, and the subsequent translocation of p52/RelB into the nucleus. The knockdown of NF-κB2/p100 by short hairpin RNA (shRNA) reduces Tax-induced IL-2-independent growth induction in CTLL-2 cells.¹²⁸ Thus, the noncanonical NF-κB pathway is also crucial for the transforming activity of Tax.

APOPTOSIS INHIBITION BY TAX

HTLV-1-infected T cells are resistant to various types of apoptosis, and this resistance is mostly mediated by Tax.^{184,248} Tax inhibits apoptosis of T cells induced by IL-2 withdrawal in an IL-2-dependent T-cell line (CTLL-2). Studies of Tax mutants (M47, M22) indicate that inhibition of apoptosis is mediated through the NF-κB pathway.¹⁵⁷ Tax activates the expression of several anti-apoptotic genes in T cells, including CTLL-2 cells through the NF-κB pathway. These genes include bcl-xl, xIAP, cIAP, and cFLIP.³⁷³ Tax also represses the expression of pro-apoptotic genes such as Bax.⁴³

ACTIVATION OF THE PI3K/AKT PATHWAY BY TAX

IL-2 activates PI3K and its downstream kinase, Akt, in normal T cells—events that are essential for apoptosis inhibition and cell growth. However, even in the absence of IL-2, HTLV-1-transformed T-cell lines show constitutive activation of the PI3K/Akt pathway. Moreover, several inhibitors of this pathway, such as LY294002 (an inhibitor for PI3K), induce growth arrest of HTLV-1-transformed T-cell lines and then induce apoptosis, suggesting that the ongoing activation of this pathway is essential for maintaining survival of HTLV-1-infected T cells.^{146,162,163} To do this, Tax directly interacts with PI3K, which consists of two subunits: the catalytic p110α subunit and the inhibitory p85α subunit. Tax directly binds to

the p85 α inhibitory subunit, causing the release of the active p110 α catalytic subunit.²⁸⁷

Activation of the PI3K/Akt pathway by Tax results in activation of the downstream target mammalian target of rapamycin (mTOR) in HTLV-1-infected T cells as well as Tax-expressing cells.⁴²² Rapamycin, an inhibitor of mTOR kinase, inhibits the growth of HTLV-1-transformed T cells and induces G1 cell cycle arrest.¹⁴⁶ This growth inhibition of HTLV-1-infected T cells is associated with reduced phosphorylations of p70S6 kinase and 4E-BP1.

G1-S PROMOTION BY TAX

In the absence of IL-2, ectopic expression of Tax in an IL-2-dependent human T-cell line (Kit225) or in PHA-activated PBMC induces cell cycle progression from G0/G1 into S phase.^{261,273,312} This activity is associated with the activation of cyclin-dependent kinase 2 (CDK2) and CDK4. CDK2 and CDK4 phosphorylate a family of retinoblastoma (Rb) proteins. The phosphorylation of Rb induces the release of the transcription factor E2F, freeing E2F to activate the expression of its target genes that control the cell cycle.

Tax has multiple distinct ways of stimulating cell cycle progression. First, Tax was found to activate CDK4 by interacting directly with p16INK4a, a CDK4 inhibitor.³⁴⁶ However, a subsequent study showed that Tax stimulates cell cycle progression even in a p16INK4a-defective T-cell line.²¹³ Indeed, Tax can also interact directly with CDK4 and its inhibitor p15INK4b, stimulating the kinase activity.^{113,220,347} Studies of Tax mutants (M22, M47) indicate that in IL-2-dependent Kit225 cells, E2F activation by Tax occurs via the NF- κ B pathway.²⁷³ E2F is a family of proteins (E2F1–E2F6). Whereas expression of E2F1 in a G0/G1-arrested fibroblast cell line induces cell cycle progression into S phase, it does not so in PHA-stimulated PBMC.²⁷³ Because Tax stimulates cell cycle progression in PHA-stimulated PBMC, in addition to E2F1 activation, Tax must have another activity that stimulates cell cycle progression in PBMC. Indeed, Tax induces the transcription of several genes associated with cell cycle regulation, including cyclin D1, cyclin D2, cyclin E, CDK2, CDK4, CDK6, and E2F1, and represses the transcription of the cell cycle inhibitor p18INK4c.^{5,155,273,305,347} In addition, knockdown experiments using short-hairpin RNA show that cyclin D2, CDK6, NF- κ B/p65, and NF- κ B2/p100 all play a role in E2F activation as well as cell cycle progression induced by Tax in Kit225 cells.¹⁵⁶ Collectively, these results suggest that Tax stimulates cell cycle progression through multiple mechanisms.

Genomic Instability in HTLV-1-Infected T Cells

HTLV-1 infected T-cells, including leukemic cells from ATL patients, have numerous genetic abnormalities such as DNA mutations, chromosomal translocations, deletions and duplications, and aneuploidy, and these genetic aberrations are linked to ATL development. For examples, homozygous deletions of p16 (CDKN2A) and p15 (CDKN2B) genes (tumor suppressor genes that regulate the cell cycle) were frequently observed in aggressive acute and lymphoma-type ATL.¹²⁴ The major viral factor that induces such genomic abnormalities is Tax, which acts via several distinct mechanisms as described later.

p53 INACTIVATION BY TAX

The tumor suppressor p53 is the “guardian of the genome” in DNA damage responses. Under normal conditions, p53 is

functionally inactive; however, upon the incidence of almost any stress, including DNA damage, p53 is accumulated, stabilized, and activated to gain competence in the transcriptional activation of genes that contribute to cell cycle arrest, apoptosis, and senescence. In HTLV-1-infected cells, such p53 functions are inactivated by Tax.^{6,248,295,412} Tax interacts with the p53 co-activator CBP/p300 and blocks its access to p53, thereby reducing the transcriptional activation function of p53.³⁴⁸ In addition, Tax induces the phosphorylation of p53 at Ser-15—a modification that triggers p53 to form an inactive ternary complex with Tax and NF- κ B/p65.^{164,295} Tax also inactivates two other p53-like proteins (p73 and p63/p51) in an HTLV-transformed T-cell line (MT-2).^{177,210} Ectopic expression of Tax in p53-negative Saos2 cells inhibits transcriptional activation of p73 and p63/p51 through the N-terminal domains. These results suggest that the inactivation of p53 and p53-related proteins is involved in the genomic instability of HTLV-1-infected cells.

ACTIVATION OF TELOMERASE BY TAX

Telomeres, the terminal sequences of chromosomes, play a crucial role in preventing chromosome abnormalities from occurring at each cell division; however, telomeres are shortened by every cell division in normal cells. In normal cells, p53-dependent replicative senescence is thus induced after a limited number of cell divisions. On the other hand, HTLV-1-immortalized cells have tricks to escape this telomere shortening, thereby avoiding replicative senescence. In HTLV-1-infected T cells, Tax activates the transcription of human telomerase reverse transcriptase (hTERT), an enzyme that synthesizes telomeric sequences and thereby extends telomeres.^{118,334} Studies using Tax mutants (G148V, M22) defective in NF- κ B activation and chromatin immunoprecipitation analysis showed that Tax induces increased binding of Sp1 and c-Myc to the hTERT promoter through the NF- κ B pathway.³³⁴

IL-2-dependent HTLV-1-immortalized T cells generally express a low amount of Tax—an amount of which may not be sufficient to maintain telomerase activity. However, IL-2 augments telomerase activity in HTLV-1-immortalized T cells. IL-2 signals inhibit the nuclear translocation of the Wilms tumor protein, an inhibitor of hTERT transcription, through a PI3K-dependent but Akt-independent pathway.³¹ The IL-2 dependence of telomerase activity in HTLV-1-infected cells suggests that continued growth of such cells in low IL-2 conditions may lead to shortened telomeres and chromosomal aberrations.

CENTROSOME AMPLIFICATION

The centrosome is a microtubule organizing center during cell division and plays a crucial role in the precise duplication and segregation of chromosomes. Whereas normal T cells have one centrosome during interphase, in HTLV-1-infected cell lines, around 30% of the cell population has more than two centrosomes, indicating that a centrosomal aberration may contribute to the chromosomal abnormalities observed in HTLV-1-infected cells.^{52,266} Such abnormal centrosomes are induced by the ectopic expression of Tax in human T cells.

This activity of Tax is mediated through its interaction with several host proteins such as TAX1BP2 and RanBP1.^{52,266} Endogenous TAX1BP2 is localized in the centrosome, and its knockdown induces centrosome amplification. Furthermore,

overexpression of TAX1BP2 reduces Tax-induced centrosome amplification. Collectively, these results indicate that Tax induces centrosome aberrations by inactivating TAX1BP2. In contrast, the knockdown of RanBP1 abrogates centrosome amplification by Tax as well as centrosome localization of Tax, indicating that RanBP1 targets Tax to centrosomes. MAD1 is another Tax-interacting protein localized in the centrosome during metaphase. Whereas the knockdown of MAD1 induces multinucleated cells, its overexpression inhibits induction of multinuclear cells by Tax.¹⁶⁹ Thus, MAD1 is also involved in the genomic instability induced by Tax in HTLV-1-infected cells.

DEFECTIVE DNA REPAIR

DNA repair activity is attenuated by Tax in HTLV-1-infected T-cell lines.^{160,179,227,238,290} Ataxia telangiectasia mutated (ATM), a member of the PI3K-like kinase family, is activated by various DNA damaging agents, and its activation is essential in initiating signaling cascades that stop DNA replication and allow the repair of damaged DNA. ATM activation by ionizing radiation (IR), and signals downstream of ATM activation, are diminished in HTLV-1-infected T-cell lines as well as cells expressing Tax alone.⁴⁹ Upon treatment with IR, both normal and Tax-expressing cells stop DNA replication; however, the interval before replication resumes is shorter in Tax-expressing cells than in the parental control cells; simultaneously, the cells expressing Tax are defective for DNA repair activity. Although the precise mechanism by which Tax blocks DNA repair has not yet been fully elucidated, Tax is known to interact with several host factors involved in DNA repair, such as DNA-dependent protein kinase, Ku, Chk1, and Chk2.^{68,284,285} In addition, Tax represses transcription of the DNA polymerase β gene, which plays a crucial role in DNA repair.¹⁶⁰

CELL CYCLE ARREST INDUCED BY TAX

Surprisingly, under certain experimental conditions, overexpression of Tax induces cell cycle arrest at G1 or G2-M as well as senescence. For instance, ectopic expression of Tax in HeLa cells or an IL-2-independent human T-cell line (supT1) induced G1 cell cycle arrest. Moreover, transient HTLV-1 infection of HeLa or SupT1 cells also induced G1 cell cycle arrest. These arrests are correlated with the Tax-dependent induction of CDK2 inhibitors (p21/waf1 and p27Kip1). In contrast, several established IL-2-independent HTLV-1-transformed T-cell lines express a high amount of p21 without cell cycle arrest, suggesting that during *in vitro* culture, HTLV-1-transformed cell lines may gain genetic change(s) that overcome cell cycle arrest. Based on these observations, it has been proposed that HTLV-1-infected cells *in vivo* are selected for their ability to escape such antigrowth effects of Tax, accumulating genetic alteration(s) during long-term HTLV-1 infection, and that this phenomenon may play a role in the numerous genetic alterations observed in HTLV-1-infected cells *in vivo*, such as chromosomal abnormalities. However, it should be noted that Tax also inactivates the growth-inhibitory functions of p21 through activating Akt: It has been reported that the activation of Akt in HTLV-1-transformed T-cell lines induces phosphorylation of p21, thereby inducing its translocation into the cytoplasm, where it is inactivated.³⁹²

REACTIVE OXYGEN SPECIES INDUCTION BY TAX

Ectopic expression of Tax in T cells stimulates the production of reactive oxygen species (ROS), which induce DNA

damage (detected by a comet assay and γ H2AX staining) and senescence (detected by β -galactosidase staining).¹⁹⁴ A ROS scavenger (N-acetylcysteine) abrogates DNA damage induced by Tax, indicating that ROS mediate the DNA damage induced by Tax. These results indicate that ROS may also contribute to the genomic abnormalities observed in Tax-expressing cells.

Inflammation Induced by Tax

INCREASED PRODUCTIONS OF CYTOKINES AND CHEMOKINES IN HTLV-1-INFECTED CELLS

One prominent feature of HTLV-1-infected T cells is the production of several cytokines and chemokines, as well as expression of their receptors. These gene inductions are mostly mediated by Tax through the NF- κ B, CREB, and AP-1 pathways^{13,20,190,250,389} and are thought to play pivotal roles in the phenotypes, activation, proliferation, differentiation, and behavior of HTLV-1-infected cells and thereby in HTLV-1 pathogenesis. For example, induction of the interleukin 2 receptor (IL-2R) complex by Tax is crucial for the immortalization of human T cells by HTLV-1.^{60,149,231} In addition, HTLV-1-infected T cells show prominent adhesion capacity, both homophilic and heterophilic, as well as cell migration activity, and they express several adhesion molecules, chemokines, and chemokine receptors involved in these functions, such as CD40, ICAM-1, OX40, and OX40L—many of which are induced by Tax in T cells.^{126,147,274,352,361} These properties would promote the resistance of HTLV-1-infected T cells to various pro-apoptotic stimuli, their migration to distant tissues through blood and lymphatic vessels, and their infiltration of tissues. Indeed, the CXCR4 antagonist AMD3100 inhibits the migration of cultured lymphoid cells from either Tax-transgenic mice or ATL patients.¹⁸³

ACTIVATION OF AP-1-DEPENDENT GENE EXPRESSION BY TAX

AP-1 activation by Tax is implicated in cell proliferation induced by Tax.²⁸⁷ The transcription factor AP-1 is transiently activated in normal T cells during antigenic stimulation, and it in turn activates several cellular genes involved in T-cell functions such as prevention of apoptosis, cytokine production, proliferation, and cell migration. In contrast, HTLV-1-infected T-cell lines have constitutive AP-1 DNA binding activity in the nucleus.⁷⁹ Such constitutive AP-1 activity is mediated by Tax. Through AP-1, Tax has been shown to activate many genes, including IL-5, IL-8, transforming growth factor beta (TGF- β), fra-1, proenkephalin, TR3/nur77, and TIMP-1.^{79,80,255,372}

AP-1 consists of protein dimers. The constituent proteins belong to two groups of transcription factors—the Fos (c-Fos, FosB, Fra-1 and Fra-2) and Jun (c-Jun, JunB, and JunD) families—and AP-1 consists of either homodimers of the Jun family or heterodimers between two groups. Among these factors, *c-fos*, *fra-1*, *c-jun*, and *junD* are all transcriptionally activated by Tax.^{79,80,255,372} Analysis of the *c-fos* promoter identified a CARG box as a Tax-inducible enhancer, where Tax interacts both with the CARG box binding protein serum response factor (SRF) and with ternary complex factor (TCF; Elk-1, SAP-1).^{81,327,343} In addition, two co-activators, CBP/p300 and P/CAF, are involved in Tax-dependent activation through the CARG box.³²⁷ The CARG box acts generally as an inducible enhancer for immediate early genes, such as *c-fos*, which are induced without *de novo* protein synthesis. Indeed, Tax, through its

action on the CARG box, induces the expression of various immediate early genes such as *c-fos*, *egr-1*, and *egr-2*.^{8,79,81}

INHIBITION OF TRANSFORMING GROWTH FACTOR BETA SIGNALING BY TAX

TGF- β is a cytokine that controls multiple cellular functions, such as cell growth inhibition, differentiation, senescence, and apoptosis, and acts as a tumor suppressor protein in solid tumors as well as leukemia/lymphoma. HTLV-1-infected T-cell lines are resistant to TGF- β -induced growth inhibition, and Tax is responsible for this resistance.^{16,208,244} TGF- β signaling is mediated through a family of transcription factors referred to as Smads. Tax, through JNK activation, induces phosphorylation of c-Jun, and phosphorylated c-Jun forms an inactive complex with Smad3.¹⁶ In addition, Tax blocks the interaction of Smads with the transcriptional co-activator p300.²⁴⁴

Deregulated microRNA in HTLV-1-Infected Cells

Although cellular microRNAs (miRNAs) are a crucial player in the host defense mechanism for clearing viral infections, many viruses have functions that counteract the antiviral activities of miRNAs. In some cases, viruses even utilize miRNAs to maintain persistent infection.³⁰² In HTLV-1-infected cells, several miRNAs are up-regulated or down-regulated relative to those in uninfected T cells.³⁰² Whereas up-regulated cellular miRNAs in HTLV-1-infected cells include miR-21, -24, -93, -130b, -146, -155, and -142-3p, down-regulated ones include miR-125a, -132, -181a, -150, and -223.^{30,291} Two miRNAs up-regulated in HTLV-1-infected T cells (miR-93 and miR-130b) target the same gene, TP53INP1, which is a p53-inducible tumor suppressor gene.⁴¹⁸ Knockdown of miR-93 and miR-130b by antagomirs in either an HTLV-1-transformed T-cell line (MT-4) or the Jurkat T-cell line increases the expression of TP53INP1 and reduces cell viability. Moreover, Tax stimulates the transcription of miR-130b. Collectively, these results suggest that Tax promotes the growth of HTLV-1-infected cells through miR-130b and TP53INP1, and that the up-regulation of certain miRNAs plays a role in the proliferation of HTLV-1-infected T cells, and thereby persistent infection and leukemogenesis.

Several miRNAs deregulated in HTLV-1-infected T cells and uncultured leukemic cells of ATL patients (miR-181a, -142, -223, and -150) are involved in hematopoiesis.³⁰ For instance, miR-181a, a gene down-regulated in HTLV-1-infected cells, is preferentially expressed in the B-lymphoid lineage in mice. Moreover, its ectopic expression in hematopoietic progenitor cells followed by *in vitro* differentiation increases the yield of the B-lymphoid lineage cells but not T-lymphoid ones. Two miRNAs (miR-150 and miR-223) are overexpressed in the PBMC of ATL patients but down-regulated in HTLV-1-transformed T-cell lines, suggesting that ATL cells and *in vitro* HTLV-1-transformed T-cell lines may originate from distinct populations. This observation may support the cancer stem cell theory for ATL development discussed later.

Distinct Activities of Tax1 Versus Tax2

HTLV-1 Tax (Tax1) and HTLV-2 Tax2 have around 80% similarity at the amino acid level and carry out many activities with equal potency. However, there are two important distinctions between the two proteins: Tax1 is associated with greater trans-

forming activity, whereas Tax2 induces IL-2 production more strongly.

THE HIGH TRANSFORMING ACTIVITY OF TAX1 RELATIVE TO TAX2

CTLL-2 is a mouse cytotoxic T-cell line, the growth of which is strictly dependent on IL-2. The lentivirus-mediated transduction of Tax1 into CTLL-2 transforms these cells, converting them from IL-2-dependent growth to IL-2-independent growth, and surprisingly, the transforming activity of Tax1 is much more potent than that of Tax2.^{128,371} These results present a simple but attractive hypothesis of the HTLV-1 pathogenesis presented later.¹²⁷ Whereas HTLV-2-infected T cells could preferentially grow and survive in conditions and/or tissues with relatively high amounts of IL-2, under low IL-2 conditions, HTLV-1-infected T cells could grow more efficiently than HTLV-2-infected cells. This distinctive characteristic of HTLV-1-infected cells would allow more clonal proliferation of infected cells *in vivo*, which is a prerequisite for ATL development. This observation may explain why HTLV-1, but not HTLV-2, is associated with ATL.

What makes Tax1 more potent than Tax2? The CTLL-2 assay identified at least two Tax1-specific functions responsible for its high transforming activity relative to Tax2: One is its interaction with selective PDZ domain proteins, and the other is its activation of the noncanonical NF- κ B2 pathway.^{128,371}

Tax1 Interaction with PDZ Domain Proteins. As mentioned earlier, studies of Tax1-Tax2 chimeras identified a PDZ domain binding motif (PBM) at the C-terminus of Tax1 (missing in Tax2) that is responsible for Tax1's high transforming activity in CTLL-2 cells. The significance of the Tax1 PBM in HTLV-1 was also indicated by the observation that deletion of the PBM from HTLV-1 (HTLV-1/ Δ PBM) abrogates its ability to persistently infect rabbits.⁴⁰⁵ Whereas the PBM is crucial for IL-2-independent growth of CTLL-2 cells, the PBM is dispensable for IL-2-dependent immortalization of primary human T cells *in vitro*, supporting the idea that the Tax1 PBM plays a role at low IL-2 conditions but not at high IL-2 conditions.

PBMs are generally located at the carboxy-terminus of cellular and viral proteins, and mediate binding with cellular PDZ (PSD-95/Discs Large/ZO-1) domain proteins. Intriguingly, PBM motifs in transforming viruses are selectively present in oncogenic viruses but not their nononcogenic relatives. For instance, human papillomaviruses (HPVs) have high-risk subtypes such as HPV16 and -18 that are associated with HPV-associated malignancies such as cervical carcinoma and low-risk subtypes that are associated only with benign hyperplastic diseases. The E6 oncoproteins of high-risk HPVs, but not low-risk ones, possess PBMs. A similar association of a PBM with a viral subtype-specific oncogenesis is also seen for human adenovirus type 9, which causes mammary tumors in rats. Interestingly, the PBMs from the oncogenic HPV E6 and the adenovirus E4-ORF1 can substitute for the Tax1 PBM in allowing Tax1 to transform CTLL-2 cells. This observation suggests that the functions of these viral PBMs and the PDZ domain proteins with which they interact are identical, and that these three oncogenic viruses utilize a common mechanism to induce malignancies. PDZ domain proteins that interact with Tax1 include Dlg1, Scribble, MAGI-3, TIP-1, and IL-16 precursor protein.^{17,271,275,399} Knockdown of Dlg1 increases the

transforming activity of Tax1 in CTLL-2 cells, suggesting that Dlg1 negatively regulates the transforming activity of Tax1.

Activation of NF- κ B2 by Tax1. Unlike Tax1, Tax2 does not activate the noncanonical NF- κ B pathway. The major defect of Tax2 here is that Tax2 cannot interact with NF- κ B2/p100.¹²⁸ Knockdown of NF- κ B2/p100 prominently reduces the transforming activity of Tax1 in CTLL-2 cells, indicating that Tax1-specific activation of the noncanonical NF- κ B pathway is crucial for the transforming activity of Tax1. In addition, transduction of p100 siRNA into large granular lymphoma cell lines derived from Tax1-transgenic mice augmented their sensitivities to pro-apoptotic stimuli and simultaneously reduced the expression of anti-apoptotic XIAP and cIAP. The leucine zipper-like region 2 (LZ-2) of Tax1 (aa 225–232) is a crucial region for Tax1-induced NF- κ B2 activation (see Fig. 48.3).³²⁶

ACTIVATION OF THE NUCLEAR FACTOR OF ACTIVATED T-CELL PATHWAY BY TAX2

Whereas Tax1 has several dominant functions over Tax2, Tax2 has one dominant function over Tax1. Ectopic expression of Tax2 in a human T-cell line (Jurkat) induces the expression of IL-2, and the activity of Tax2 is much more potent than that of Tax1 in this respect.²⁶⁴ Similarly, HTLV-2–infected T-cell lines, but not HTLV-1–infected ones, constitutively produce IL-2 protein in the culture supernatant. Importantly, anti-IL-2R antibodies inhibit the proliferation of HTLV-2–infected T-cell lines, suggesting that the IL-2/IL-2R autocrine loop is essential for this proliferation. IL-2 gene induction by Tax2 in HTLV-2–immortalized T cells is mediated through the nuclear factor of activated T cells (NFATs), especially the NFATp component. In normal T cells, NFAT is retained in the cytoplasm in an inactive, phosphorylated form, and its dephosphorylation (by the phosphatase calcineurin) induces its translocation into the nucleus and allows it to activate transcription of its target genes. Cyclosporine A, an inhibitor of calcineurin, abrogates IL-2 expression induced by Tax2, indicating that Tax2 activates IL-2 production by targeting calcineurin or elements upstream of it.

Tax3 and Tax4

HTLV-3 and HTLV-4 encode Tax3 and Tax4, respectively. Amino acid comparison of these Tax proteins indicates that Tax3, but not Tax4, has a PBM, and Tax3 has been shown to bind to the PDZ domain protein Dlg4.⁵¹ On the other hand, in the LZ-2 region (essential for NF- κ B2 activation by Tax1), Tax3 and Tax4 show more homology to Tax2 than to Tax1 (see Fig. 48.3). Therefore, these four HTLVs are classified into at least three distinct groups based on the PBM and the LZ-2 region.

In Vitro Immortalizing and Transforming Activities of Tax1

Tax immortalizes primary human or rat T cells in the presence of IL-2. Analysis of Tax mutants (M22, M47) indicates that the NF- κ B pathway is crucial for immortalization of T cells. When *tax* gene is transduced into PBMCs by a retroviral vector, Tax preferentially immortalizes CD4+ T cells. Interestingly, a Tax mutant defective in activating the CREB pathway (M47) preferentially immortalizes CD8+ cells but not CD4+ cells. These results have been confirmed by studies using whole virus: an HTLV-1 mutant carrying the same Tax mutation

(M47, M22). These results suggest that the NF- κ B pathway plays a major role in immortalization of T cells by Tax, whereas the CREB pathway is involved in the preferential immortalization of CD4+ cells.³⁰⁰

Tax Activities in Animal Models

Tax-transgenic animals (mice or rats) develop various diseases such as CD4+ T-cell leukemia/lymphoma, natural killer (NK) cell lymphoma, thymoma, and neurofibroma.^{107,123,260,272} For instance, mice transgenic for *tax* regulated by the mouse lymphocyte-specific tyrosine kinase (Lck) proximal or distal promoter both developed T-cell leukemia/lymphoma: the former, a pre-T-cell lymphoma/leukemia with a double negative (CD4–CD8–) phenotype, and the latter, a mature single-positive (CD4+ or CD8+) T-cell leukemia/lymphoma.^{123,272} Intriguingly, cancer stem cells (CSCs) were identified from the Lck (proximal)-tax-transgenic mice in a minor population of CD38–/CD71–/CD117+ cells by inoculating the splenic lymphomatous cells into immune-deficient (NOD/SCID) mice.⁴¹³ Such CSCs originated from pro-T cells or early hematopoietic progenitor cells. Inoculation of HTLV-1–infected or Tax1-transduced human CD34+ hematopoietic stem/progenitor cells (HPS/PC) into humanized SCID mice results in the development of CD4+ T-cell lymphoma.²³ These results suggest that HTLV-1 infection of CD34+ HPS/PC may play a role in ATL development.

NF- κ B activation plays a crucial role in the oncogenic activity of Tax in animals. For instance, the Tax-transgenic mice developing NK cell lymphoma show constitutive activation of NF- κ B, and the inhibition of NF- κ B by anti-NF- κ B therapeutics perturbs the progression of the disease.²³⁶

In addition to malignancies, Tax transgenic mice develop chronic inflammatory diseases such as rheumatoid arthritis, dermatitis, and exocrinopathy resembling Sjögren syndrome.^{105,153} These diseases are more frequent in HTLV-1–infected individuals than HTLV-1–negative ones. Autoimmunity through molecular mimicry of HTLV-1 proteins to host proteins is proposed to be a mechanism in the development of HTLV-1–associated chronic inflammatory diseases including HAM/TSP. HAM/TSP patients possessed antibody to hnRNP-A1 expressed in neurons, which is cross-reactive to Tax, and this antibody is associated with impaired neuronal function.²¹⁸ Intriguingly, autoimmunity against various host factors such as type II collagen is detected in Tax transgenic mice, and this activity is correlated with the development of these chronic inflammatory diseases.¹⁵² Cell surface Fas and its ligand FasL play crucial roles in the elimination of autoreactive T cells through FasL-induced apoptosis. Peripheral T cells derived from Tax-transgenic mice are more resistant to FasL-mediated apoptosis than those from nontransgenic mice. Thus, Tax, through inhibiting the elimination of autoreactive T cells by the Fas/FasL system, may play a role in inducing autoimmunity in these mice and in the development of HTLV-1–associated inflammatory diseases.¹⁹⁵ However, these transgenic mice that developed arthritis with resistance to Fas/FasL signal express both Tax and HBZ (see later discussion). It remains obscure whether this phenotype is actually caused by Tax, alternatively either by HBZ or the combination.

Tax-transgenic mice regulated by a conditional lymphocyte-specific Tet-off-*EuSR α* promoter developed lethal inflammatory

skin diseases of progressive alopecia and hyperkeratosis together with systemic lymphadenopathy and splenomegaly.²⁰³ Skin manifestations such as inflammatory dermatitis are commonly observed in HTLV-1-associated diseases; thus, these results suggest that Tax plays a role in inflammatory skin disease in HTLV-1 infection. Studies of mice carrying mutant *tax* genes (M47, M22) indicate that the NF- κ B pathway is sufficient for inducing all manifestation in these mice, whereas the CREB pathway is dispensable. Consistent with this observation, these mice highly express a number of genes associated with inflammation (such as numerous cytokines and chemokines), which are regulated by the NF- κ B pathway.

Posttranslational Modification and Stability of Tax

Tax is modified by ubiquitination, phosphorylation, and sumoylation, and these modifications regulate the stability, activities, and subcellular localization of Tax.

UBIQUITINATION

Tax has 10 lysine (K) residues, referred to as K1 through K10, throughout the protein. K4 through K10 are the main targets of both monoubiquitination and polyubiquitination.^{205,259,286} Ubiquitinated Tax is localized both in the cytoplasm and in the nucleus; however, the amount in the cytoplasm is greater than that in the nucleus. Ultraviolet radiation of cells induces massive monoubiquitination of Tax, and under these conditions, Tax is exclusively localized in the cytoplasm.⁸⁷ Tax (K4–K8) is involved in the interaction with IKKs, because mutation of these residues in a K(4-8)-R (Arg) Tax mutant abrogates the interaction with IKKs as well as translocation of NF- κ B/p65 into the nucleus. K7 and K8 are especially crucial for Tax activation of the NF- κ B pathway but not the CREB/ATF pathway.

SUMOYLATION

Tax is sumoylated by all three isoforms of SUMOs (SUMO-1, SUMO-2, SUMO-3).^{205,259} The molecular weights of Tax conjugated with HA-tagged SUMOs indicate that Tax is conjugated with one to three SUMO monomers. An NF- κ B-activation-defective Tax mutant (M22) is not sumoylated, suggesting that sumoylation of Tax plays a positive role in NF- κ B activation. Analysis of lysine mutations indicates that K7 and K8 of Tax are the major sites of sumoylation. Sumoylated Tax conjugated with HA-tagged SUMO-3 was predominantly detected in the nuclear bodies of 293T cells, whereas ubiquitinated Tax is localized diffusely in the nucleus as well as the cytoplasm—an observation suggesting that Tax sumoylation may control the nuclear localization of Tax.

PHOSPHORYLATION

Tax is a constitutively phosphorylated protein, and its phosphorylation is augmented by treatment of HTLV-1-infected T cells with PMA, an activator of PKC.⁷⁶ Tax is phosphorylated at multiple sites such as Ser-10, Ser-77, Thr-48, Thr-184, Thr-215, Ser-274, Ser-300, Ser-301, and Ser-336.⁶⁹ Of these, mutation of Thr-215 or double mutation of Ser-300 and Ser-301 abrogates the activation of both the CREB and NF- κ B pathway, whereas mutation of Thr-48 blocks activation of the NF- κ B pathway but not of CREB. Phosphorylations of Ser-300 and Ser-301 are also involved in the localization of Tax in nuclear bodies.³²

PROTEIN STABILITY

Pin1 is a peptidyl-prolyl *cis-trans* isomerase that regulates the function and stability of several proteins. Tax induces the expression of Pin1 in HTLV-1-infected T-cell lines and moreover interacts with Pin1.²⁸⁸ Pin1 interacts selectively with phosphorylated Tax at Ser-160 at the mitotic cell phase.¹⁶⁵ Modification by Pin1 results in the increased stability of Tax, thereby augmenting transcriptional activation through the NF- κ B and CREB pathways. Consistent with this observation is the finding that overexpression of Pin1 increases the transforming activities of Tax to CTLL-2 as well as NIH-3T3 cells.

p12/p8

p12 is encoded by the singly spliced mRNA of HTLV-1 ORF1.^{58,200,263} p12 is a highly hydrophobic membrane protein of 99 amino acids, and it is localized in the endoplasmic reticulum (ER) and Golgi complex.^{64,199,384} p12 has a noncanonical ER retention/retrieval motif, two putative transmembrane (TM) domains, four putative proline-rich (PXXP) Src-homology 3 (SH3)-binding domains, two putative LZ motifs, and a putative adaptin motif.^{77,83,263} (Fig. 48.5). When ectopically expressed in HeLa cells, p12 forms a homodimer through its TM domains.³⁷⁰

A p12-deficient HTLV-1 mutant (p12 mutation of Met-1 to Leu and a HBZ mutation of His-151 to Gln) had reduced infectivity of DCs, and when rhesus macaques were infected with it, viral propagation and persistent infection were poorly established.^{365,381} On the other hand, this mutant HTLV-1 produced infectious viruses comparable to wild-type HTLV-1, immortalized primary human T cells *in vitro*, and established persistent infection in rabbits. Thus, DC infection with HTLV-1 appears to be critical for persistent infection in macaques, and p12 may play a role in this process.

Effect of p12 on T-Cell Activation and Proliferation

p12 activates Ca²⁺ signaling in T cells.^{63,64} Ectopic overexpression of p12 in a T-cell line increases intracellular Ca²⁺ levels, stimulating dephosphatase calcineurin to dephosphorylate NFAT and then NFAT to activate transcription of genes such as IL-2.^{7,189} p12 increases intracellular Ca²⁺ concentration by interacting with two ER resident proteins—calnexin and calreticulin—that regulate Ca²⁺ release from the ER.⁶⁴ In addition, p12 interacts directly with calcineurin. Because HTLV-1-transformed T-cell lines generally do not exhibit constitutive NFAT binding to the IL-2 promoter,²⁶⁴ NFAT appears to be only transiently activated by p12 at a particular phase of HTLV-1 infection, such as an initial infection.

p12 in T cells can stimulate the IL-2 signaling pathway downstream of the IL-2R. p12 interacts with the beta and gamma-c chain of the IL-2R and enhances the phosphorylation of STAT5 and its DNA binding, thereby augmenting transcription.²⁴⁷ Expression of p12 in a human T-cell line transformed by a p12-defective HTLV-1 mutant augments colony formation in soft agar in low IL-2 conditions.

p12-Induced Attenuation of the Host Immune Response

p12 is implicated in reduced host immunity to HTLV-1-infected cells. HTLV-1-infected primary CD4⁺ T cells are resistant to autologous NK cell-mediated killing.³⁸⁵ Such killing is initiated by binding of NK to target cells via adhesion

FIGURE 48.5. Schematic structure, functional domains, and functions of p12/p8. A: The protease cleavage sites are indicated. The known functions of p12/p8 are summarized. **B:** p8 induces cellular conduit formation, which is involved in HTLV-1 transmission. TM, putative transmembrane domain; LZ, leucine zipper-like structure; SH3, Src-homology 3; ER retention, endoplasmic reticulum retention signal.

molecules ICAMs. HTLV-1 infection reduces the expression of ICAM-1 and ICAM-2 in primary CD4⁺ T cells, thereby reducing NK cell binding. Lentivirus-mediated expression of p12 in primary CD4⁺ T cells down-modulates expression of ICAM-1 and ICAM-2. In addition, p12 can reduce CTL-mediated killing.¹⁷² p12, through interaction with the major histocompatibility complex (MHC) class I heavy chain, inhibits its interaction with β 2-microglobulin, thereby inducing the proteasome-dependent degradation of MHC class I.

Functions of p8

Proteolytic cleavage of p12 generates the C-terminal product p8, which may mediate HTLV-1 transmission.³⁸⁵ The cleavage of p12 removes the ER retention/retrieval motifs, and thus p8 is localized to the T-cell membrane (see Fig. 48.5). Upon T-cell receptor activation, p8 is recruited into the immunological synapse. Comparison of p8-positive and -negative HTLV-1 indicates that p8 increases cell-to-cell contact and induces lymphocyte function-associated antigen-1 (LFA-1) mediated cell clustering, augmenting the number and length of conduits (filopodia-like membrane extensions), and thereby enhancing HTLV-1 transmission.

p13

p13 is encoded by the singly spliced monocistronic mRNA of the HTLV-1 x-II ORF.^{329,331} p13 is a highly basic protein of 87 amino acids and is identical to the C-terminal 87 amino acids of p30. p13 has the following domains: an amphipathic alpha helix (residues 20–35), a mitochondrial targeting signal (MTS) (residues 21–30), a TM region (residues 30–40), and several PXXP motifs (Fig. 48.6).

A p13-defective HTLV-1 virus (with a mutation of the p13 initiation codon) showed comparable infectivity of rabbit PBMC to that of wild-type virus; however, the mutant virus could not establish infection in rabbits *in vivo*, as measured by viral loads and antibody responses, indicating that p13 plays a still-unknown role in establishing HTLV-1 infection *in vivo*.¹³⁴

p13 is localized mostly in the inner mitochondrial membrane, and its ectopic expression in isolated mitochondria induces mitochondrial swelling, depolarization, increased respiratory chain activity, and production of ROS, through activation of the inward K⁺ current.^{33,330,331} p13 also induces ROS production in primary quiescent T cells.

HBZ

The viral genes that are transcribed from the 5' LTR are encoded by the plus strand of the provirus (sense transcript). However, an antisense transcript encoded by the minus strand has also been identified in HTLV-1.^{45,88,207,252,308} The antisense transcript, originating from the 3' LTR, encodes the *HTLV-1 bZIP factor* (HBZ) gene.

Transcription of the HBZ Gene

Two major forms of the HBZ RNA have been reported: a spliced form (*sHBZ*) and an unspliced form (*usHBZ*). The first

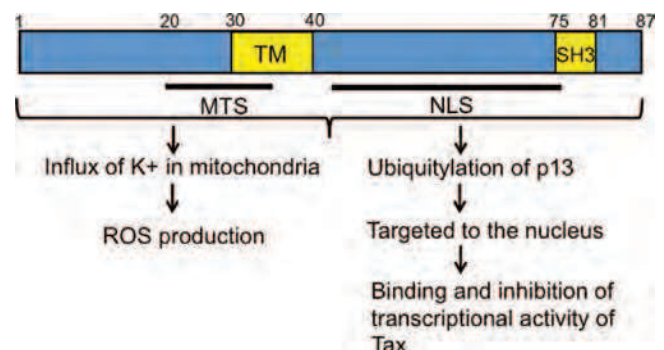

FIGURE 48.6. Schematic structure, functional domains, and functions of p13. The functions of p13 are summarized. TM, putative transmembrane domain; MTS, mitochondrial targeting signal; SH3, Src-homology 3; NLS, nuclear localization signal; LZ, leucine zipper-like structure.

FIGURE 48.7. Transcription of the *HBZ* gene. There are two isoforms of the *HBZ* gene transcripts: spliced and unspliced forms. Transcription of the *HBZ* gene depends on Sp1, whereas the transcription from 5' LTR is highly inducible by Tax.

exon of the *sHBZ* gene transcript is located in the R region of the 3' LTR (Fig. 48.7A). Transcriptional start sites for *sHBZ* are scattered in the U5 and R regions of the 3' LTR, an observation that is consistent with the finding that the predicted promoter was TATA-less.⁴²⁰ Three Sp1 binding sites are critical for transcription of the *HBZ* gene. Because Sp1 is a well-known regulator of housekeeping genes, transcription of the *sHBZ* gene may be constitutive and relatively constant. As described later, levels of *HBZ* gene transcript are better correlated with provirus load than those of the *tax* gene transcript,³⁰³ confirming that the *HBZ* gene is constitutively expressed in HTLV-1-infected cells. Thus, transcription from the minus strand stands in contrast to that from the plus strand, which is highly inducible by Tax.

The difference between *sHBZ* and *usHBZ* is only a few amino acids, as shown in Figure 48.7B. The spliced transcript of *HBZ* is translated into a polypeptide of 206 amino acids, whereas the protein product of unspliced *HBZ* is a polypeptide of 209 amino acids. The expression level of *sHBZ* RNA is much higher than that of *usHBZ* RNA,³⁷⁹ and the half-life of *sHBZ* protein is much longer than that of *usHBZ*.⁴²⁰ Taken together, these data indicate that expression levels of *sHBZ* are much higher than those of *usHBZ*, suggesting that *sHBZ* is more important than *usHBZ* for HTLV-1-infected cells and ATL cells. TREs in the U3 region act as enhancers for sense transcription of viral genes by interaction with Tax. Similarly, Tax activates transcription of the *HBZ* gene through binding to TREs.^{206,420}

Functions of HBZ

HBZ protein is localized in the nucleus with a speckled pattern.¹³⁹ HBZ has three domains: the activation, central, and bZIP domains (Fig. 48.8). HBZ was originally reported to suppress Tax-mediated viral gene transcription from the 5' LTR via interaction with CREB2 and c-Jun.^{25,88,232} Further, HBZ interacts with various host factors with bZIP domain, including CREB, JunB, ATF-1, and ATF-3, and hinders their transcriptional activation.^{25,108,138,209} Conversely, interaction of HBZ with JunD activates transcription of target genes.³⁶⁷ Furthermore, HBZ enhances the TGF- β /Smad pathway by interaction with Smad2/3 and p300.⁴³¹ Importantly, HBZ does not interfere with expression of TGF- β /Smad target genes associated with cell cycle and proliferation. HBZ also selectively inhibits the classical NF- κ B pathway by inhibiting DNA binding of p65 and promoting the degradation of p65.⁴³²

Leukemic cells in two-thirds of ATL cases express FoxP3,¹⁸⁰ which is a master molecule of regulatory T (Treg) cells, suggesting that ATL is a malignant disease of Treg cells. Furthermore, in HTLV-1-infected individuals, the proportion of HTLV-1-infected cells is higher in Treg populations,³⁶⁹ indicating that HTLV-1 is associated with Treg cells. HBZ induces Foxp3 expression in T cells, and its induction is enhanced in the presence of TGF- β .³⁰⁹ This accounts for why HTLV-1 is associated with Treg cells. Furthermore, HBZ interacts with Foxp3 protein and impairs its functions.³⁰⁹ Thus, HBZ increases the number of functionally impaired Treg cells and may lead to the development of malignancy derived from Treg cells.

FIGURE 48.8. Functions of HBZ. HBZ has three domains: activation, central, and bZIP. The HBZ protein exerts a variety of functions by interacting with host factors. On the other hand, *HBZ* RNA promotes proliferation via up-regulation of the *E2F1* gene.

Interplay Between HBZ and Tax

For many pathways, HBZ has activities that oppose Tax (Fig. 48.9). Tax can activate both the canonical and noncanonical NF-κB pathways, whereas HBZ suppresses only the canonical pathway. These two pathways differentially control genes with anti-apoptotic functions in lymphoma cell lines. Expression of both Tax and HBZ could thus lead to predominant activation of the noncanonical pathway, a phenomenon that might be implicated in proliferation of ATL cells. Expression of Tax induces cell senescence via enhanced expression of CDK inhibitors p21 and p27.⁴³³ As a mechanism, p53 induces this senescence by stabilization of p27 protein and p21 mRNA. Co-expression of HBZ with Tax delay or prevent the Tax-induced senescence, leading to cell proliferation. Similarly, HBZ enhances TGF-β/Smad signaling, whereas Tax suppresses this pathway. Thus, it is assumed that HBZ activity is intricately interregulated with that of Tax, modulating viral gene expression, promoting cell proliferation, and leading to oncogenesis.

HBZ Promotes T-Cell Proliferation

Suppression of *HBZ* gene expression by shRNA inhibits proliferation of ATL cell lines.^{15,308} Expression of *HBZ* in transgenic

mice increases the number of T cells, whereas suppression of *HBZ* expression decreases tumor formation and infiltration of ATL cells.¹⁵ Thus, *HBZ* expression is associated with proliferation of ATL cells *in vivo* and *in vitro*. Mutation analysis of the *HBZ* gene showed that *HBZ* RNA, rather than HBZ protein, has a growth-promoting effect on T cells.³⁰⁸ Only *sHBZ* RNA, not *usHBZ* RNA, promotes the proliferation of T cells, indicating that the first exon of the *sHBZ* transcript is critical for this activity.⁴²⁰ This exon overlaps with the Rex responsive element (RxRE) in the R region of 3' LTR. Recall that the RxRE region forms a stem-loop structure that binds to Rex, and Rex promotes the export of viral RNA with an RxRE region. Kinetic analysis of viral mRNA shows strong nuclear retention of *HBZ* mRNA,²⁹⁸ which might be important for growth-promoting activity of *sHBZ* mRNA. Thus, *sHBZ* RNA promotes proliferation of T cells via a region that can form a strong stem-loop structure. Further details of how *sHBZ* RNA promotes proliferation remain to be elucidated.

APH-2

An antisense transcript similar to *HBZ* has been discovered in HTLV-2 and named antisense protein of HTLV-2 (APH-2).¹¹²

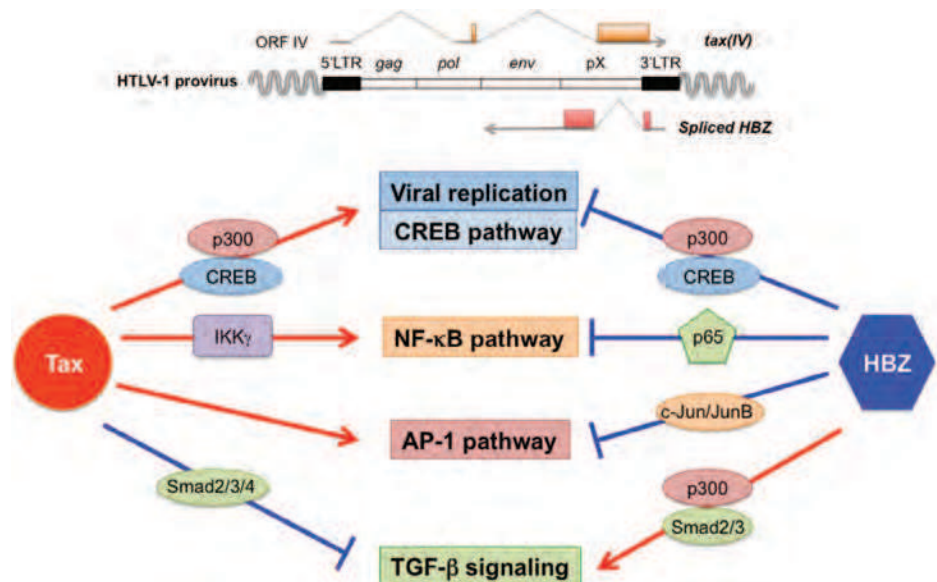

FIGURE 48.9. Interplay between Tax and HBZ. Interplays between Tax and HBZ on various pathways are shown. In most pathways, HBZ has opposite effects to Tax.

The *APH-2* gene encodes a 183 amino acid polypeptide that is localized in the nucleus. Although APH-2 does not have a bZIP domain, APH-2 interacts with CREB and represses Tax2-mediated transcription from the 5' LTR of HTLV-2. Both HBZ and APH-2 have suppressive effects on transcription of sense viral genes, although any other functions of APH-2 remain to be elucidated.

PATHOGENESIS AND PATHOLOGY

Entry into the Host

HTLV-1 transmission usually occurs through cell-to-cell contact of HTLV-1–uninfected cells with HTLV-1–infected cells, and cell-free viruses are poorly infectious. Thus, cell-free blood products do not transmit HTLV-1.²⁷⁸ HTLV-1 is primarily transmitted from infected mother to child through breast-feeding. In addition, sexual contact and blood transfusion are additional routes of transmission. Sexual transmission is mostly from male to female; transmission from female to male is far less efficient.³⁴⁰

HTLV-1 entry into susceptible cells begins with the binding of the HTLV-1 envelope proteins to a viral receptor on the membrane of the host cell, and it is followed by the fusion of viral and cell membranes.^{24,95,229} The HTLV-1 envelope protein (Env) is synthesized as a 68 kD polypeptide precursor and is cleaved to produce two subunits: the surface glycoprotein (SU) of 46 kD (gp46) and the TM glycoprotein of 21 kD (gp21). Mature envelope proteins on the virions are trimers, consisting of three SUs and three TMs linked by disulphide bonds. The cytoplasmic domain of gp21 controls envelope-mediated syncytium formation and cell-to-cell HTLV-1 entry.^{188,294} The C-terminus of gp21 contains a PDZ-domain protein binding motif, and the deletion of this motif reduces the stability of Env.³⁷ In addition, the Y-S-L-I motif in the cytoplasmic domain of gp21 is crucial for cell-to-cell HTLV-1 transmission.⁶¹

Functions of Glucose Transporter 1 in HTLV-1 Entry

Two host proteins have been identified as acting as HTLV-1 receptors: glucose transporter 1 (GLUT-1) and neuropilin-1

(NRP-1) (Fig. 48.10). Of them, the GLUT-1 glucose transporter was the first identified.^{59,174,192,230} GLUT-1 interacts with the receptor binding domain (RBD) (the first 215 aa) of HTLV-1 Env and HTLV-2 Env. Knockdown of GLUT-1 by siRNA resulted in reduced binding of the HTLV-1 and HTLV-2 RBD to the cells as well as reduced infection by HTLV-2-env pseudotype virus, and this was rescued by overexpression of GLUT-1 but not GLUT-3, another glucose transporter family member. In addition, polyclonal chicken antibody against the extracellular loop domain of GLUT-1 inhibited Env-mediated fusion as well as infection.¹⁷¹ Specific regions of GLUT-1 mediated the binding to HTLV-1 Env and virus entry into cells.²²⁸

Functions of Neuropilin-1 in HTLV-1 Entry

NRP-1 also functions as an HTLV-1 receptor.⁹⁶ Overexpression of NRP-1 in the cells expressing a low amount of endogenous NRP-1 augments HTLV-1 Env-mediated infection, and NRP-1 knockdown by siRNA in 293T cells reduces HTLV-1 Env-mediated infection. Interestingly, NRP-1 co-localizes with the Env protein at cell membranes and forms a complex with GLUT-1. Moreover, this complex formation is augmented by the expression of Env protein, suggesting that NRP-1 and GLUT-1 make a HTLV-1 receptor complex that mediates HTLV-1 binding and entry (see Fig. 48.10A), as CD4 and chemokine receptors do for human immunodeficiency virus (HIV) infection. In addition, HTLV-1 might differentially utilize GLUT-1 and NRP-1 in a cell-type dependent manner. For instance, knockdown of GLUT-1 reduced Env-mediated fusion in HeLa cells but not in U87 glioblastoma/astroglioma cells.¹⁷⁰

In addition to GLUT-1 and NRP-1, HTLV-1 infection is enhanced by several host proteins, such as ICAM-1, ICAM-3, and VCAM-1, in various settings. Heparan sulfate proteoglycans (HSPGs) have been shown to be crucial for efficient HTLV-1 binding and infection of CD4+ T cells.^{174,293} HTLV-1 virions and purified gp46 proteins bound to HSPG on CD4+ T cells, and the binding was abrogated by treatment of target cells with heparan-sulfate lyase. Moreover, soluble heparin blocked HTLV-1 infection of susceptible cells.

FIGURE 48.10. The HTLV-1 receptor complex and the current model of HTLV-1 entry. **A:** (1) The HTLV-1 envelope protein (Env) attaches to heparan sulfate proteoglycans (HSPGs) on the target cell, which increases the local concentration of the viruses at the cell surface. (2) HTLV-1 Env then binds to neuropilin-1 (NRP-1), and this binding induces a conformational change of Env that facilitates its interaction with glucose transporter 1 (GLUT-1). (3) The formation of a ternary complex of Env, NRP-1, and GLUT-1 induces a conformational change of Env that triggers the fusion of the viral and cell membranes. **B:** The contact site between an HTLV-1-infected cell and a target cell forms a special structure referred to as the virological synapse (VS). VS formation involves polarization of the microtubule-organizing center near the site of cell-to-cell contact in the infected cell. **C:** HTLV-1-infected cells contain infectious virions in extracellular carbohydrate-rich assemblies, and their removal reduces cell-to-cell HTLV-1 transmission. These virion-containing assemblies resemble bacterial biofilm in structure and composition.

Determinants of Tropism of HTLV-1 and HTLV-2 Entries

HTLV-1 and HTLV-2 preferentially immortalize CD4+ T cells and CD8+ T cells *in vitro*, respectively, and they are preferentially detected in CD4+ T cells and CD8+ T cells in infected individuals, respectively.^{145,299,300,390} These observations may reflect the distinctive infection tropism of HTLV-1 versus HTLV-2.¹⁷⁵ Whereas HTLV-1 infects primary CD4+ T cells much more efficiently than CD8+ T cells, HTLV-2 behaves in the reverse manner. These tropisms may be owing to distinctive viral receptor usages. Unlike GLUT-1, HSPG is not required for HTLV-2 infection, because reduction of HSPG by HS lyase has little effect on HTLV-2-Env-mediated infection. Activated primary human CD4+ T cells and CD8+ T cells express different levels of HTLV-1 receptors, and CD4+ T cells express

much more HSPG than CD8+ T cells, whereas CD8+ T cells express much more GLUT-1 than CD4+ T cells. Collectively, these results suggest that HTLV-1 and HTLV-2, through distinct usages of GLUT-1 and HSPG, preferentially infect CD4+ T cells and CD8+ T cells, respectively, thereby preferentially immortalizing selective cell types. The study of recombinant viruses has demonstrated that the envelope genes of HTLV-1 and HTLV-2 are the major determinant for immortalization tropism (CD4+ vs. CD8+) of human T cells.⁴⁰⁴ In addition, it is noteworthy that HTLV-3 utilizes GLUT-1 as a viral receptor; however, neither NRP-1 nor HSPG is required for infection, and HTLV-3 binds not only activated primary T cells but also resting ones.⁴⁰⁴ These results suggest that these three HTLVs acquired distinct entry mechanisms after diversification from their common ancestor.

DCs are implicated as key players for HTLV-1 transmission. Whereas cell-free HTLV-1 is poorly infectious for CD4+ T cells, it efficiently infects plasmacytoid and myeloid DCs.^{48,159,176} Such HTLV-1-infected DCs can immortalize CD4+ T cells, indicating that DCs can act as intermediate reservoirs for HTLV-1 infection of CD4+ T cells. Cell-free HTLV-1 infection of DCs is enhanced by DC-specific ICAM-3-grabbing nonintegrin (DC-SIGN), which interacts with ICAM-2 and ICAM-3 but not HTLV-1 Env. HSPG and NRP-1 are involved in the transfer of HTLV-1 from DCs to CD4+ T cells. These results suggest that DCs play a crucial role in the early phase of HTLV-1 transmission.

Virological Synapse and Biofilm-Like Assemblies in HTLV-1 Entry

During cell-to-cell HTLV-1 transmission, the site of contact between an HTLV-1-infected cell and a target cell forms a special structure called the *virological synapse* (VS; named thus because of its similarity to the immunological synapse)^{24,144,173,292} (see Fig. 48.10B). VS formation involves polarization of the microtubule-organizing center (MTOC) near the site of cell-to-cell contact in the infected cells. ICAM-1 and Tax appear to play a role in polarization of the MTOC during cell-to-cell transmission.

Extracellular carbohydrate-rich assemblies attached to the surfaces of HTLV-1-infected cells contain infectious virions, and their removal prominently reduces cell-to-cell HTLV-1 transmission²⁸³ (see Fig. 48.10C). These virion-containing assemblies produced by HTLV-1-infected cells resemble bacterial biofilm in structure and composition, and contain collagen, agrin, tetherin, and galectin-3. One of these proteins, tetherin, negatively controls HIV infection through inhibiting the release of HIV virions, suggesting that biofilm-like assemblies may also contain inhibitors of HTLV-1 infection.⁶⁷

Site of Primary Replication and Spread of the Virus

After transmission by breast milk, sexual contact, or blood transfusion, HTLV-1 infects DCs and/or T-cells *in vivo*, and spreads via cell-to-cell contact. HTLV-1-infected cells proliferate and spread in the body. In experimentally infected squirrel monkeys (*Saimiri sciureus*), HTLV-1 provirus was detected first in PBMCs and then in lymphoid organs including lymph node, spleen, and bone marrow.¹⁸⁶ This shows that HTLV-1 spreads in lymphoid tissues. In HTLV-1-infected individuals, bone marrow has been identified as a reservoir for HTLV-1.²¹⁷

HTLV-1 virions cannot be detected in HTLV-1-infected individuals. Instead, HTLV-1 infected cells proliferate *in vivo*: HTLV-1 copy number increases by mitosis of infected cells, whereas HTLV remains in the form of a provirus integrated in the host genome. Expression of adhesion molecules, including ICAM-1 and LFA-1, is up-regulated on HTLV-1-infected cells.⁸² In HAM/TSP patients and HTLV-1 carriers, infected cells not only circulate in blood but also infiltrate into skin, lung, and intestine. Thus, HTLV-1-infected cells persist and spread *in vivo*. If infected cells have proinflammatory properties, their proliferation and activation might induce inflammatory diseases.

Cells and Tissue Tropism

GLUT-1, a receptor for HTLV-1, is ubiquitously expressed on cells. HTLV-1 can infect various cells, including T cells, B cells, macrophages, myeloid cells, and fibroblasts *in vitro*.²⁰¹ However, the provirus is detected predominantly in T cells *in vivo*. Most infected cells are CD4+ T cells, especially effector/memory T cells and Treg cells.^{299,369,415} Approximately 10% of the provirus is detected in CD8+ T cells,^{253,415} indicating that CD8+ T cells are also a reservoir of this virus. These “preferences” may reflect either a true viral tropism or postinfection events that alter infected cells—events that are related to certain functions of HTLV-1 encoded proteins. For example, in transgenic mice expressing the *HBZ* gene, the population of effector/memory T cells and Treg cells is increased.³⁰⁹ HBZ induces Foxp3 expression, indicating that HBZ can convert infected T cells to Treg cells.³⁰⁹ Furthermore, it is thought that Tax stimulates the proliferation of CD4+ T cells. CD4+ T cells can be immortalized in *tax* gene transgenic mice by immune activation,³⁴⁹ perhaps because Tax expression synergistically augments signaling through the T-cell receptor.²³¹ Furthermore, a retroviral vector expressing Tax immortalizes CD4+ T cells *in vitro*.⁴ Thus, HBZ and Tax are considered to be responsible for the apparent cell tropism of HTLV-1.

Immune Response and Persistence

Persistence of HTLV-1-Infected Cells *In Vivo*

Free HTLV-1 virions are not detected *in vivo*. Instead, HTLV-1 spreads via cell-to-cell contact, and infected cells proliferate. Virus burdens are measured by provirus load (i.e., the number of infected cells). Compared with the highly variable sequences of HIV, HTLV-1 proviral sequences remain stable in infected individuals.^{92,382} Because proviral sequence variations are caused by error-prone reverse transcriptase during viral replication, the stability of proviral sequences indicates that HTLV-1 replicates primarily by mitosis of infected cells instead of by viral replication. Provirus load varies less than 5-fold within the same infected individuals during the clinical course. However, provirus load differs more than 1000-fold from one infected host to another, indicating that provirus load is controlled by host factors *in vivo*.⁷²

Integration sites of HTLV-1 provirus are random in the host genome.^{66,282} Therefore, clonal proliferation can be demonstrated by identifying integration sites of the HTLV-1 provirus.^{47,71} Infected T-cell clones in seroconverters were more variable than long-term carriers,³⁶⁰ indicating that over time, conditions within the host (immune response, etc.) select certain infected T-cell clones. Consistent with this finding, identifica-

tion of integration sites by high-throughput sequencing shows that negative selection is predominant in chronic infection.¹⁰⁰

Implication of HTLV-1 Provirus Load in Pathogenesis

Provirus load is an important parameter of HTLV-1 associated diseases. Higher provirus load was reported in patients with HAM/TSP and uveitis compared with asymptomatic carriers.^{254,279} High provirus load was also reported to be a possible risk factor for ATL.^{135,154} In HAM/TSP patients, an increased number of infected clones, rather than increased cell numbers in each clone, is the main contributor to increased provirus load.¹⁰⁰ In HAM/TSP and other HTLV-1-associated inflammatory diseases, HTLV-1-infected cells and lymphocytes reacting to viral antigens infiltrate into various tissues, including skin, lung, intestine, and spinal cord. Cytokines produced by infected cells and reacting lymphocytes likely induce the tissue damage that characterizes these diseases.²⁸⁰ In HAM/TSP, CD4+CD25+CCR4+ T cells produce IFN- γ , which may be implicated in the pathogenesis of this disease.⁴¹⁰

Immune Response to HTLV-1

The immune response is a major factor in determining the provirus load within an infected individual. The balance between viral gene expression and the host immune response likely determines the number of infected cells. Because Tax is a major target of CTLs,^{158,178} Tax-expressing cells are rapidly eliminated. However, transcription of the *tax* gene from the 5' LTR is suppressed *in vivo*.¹¹⁷ *In vitro* culture of HTLV-1-infected cells elicits a rapid recovery of the *tax* gene expression. Depletion of CD8+ T cells in cultured cells enhances Tax expression, indicating that CTL activity partially limits viral gene expression.¹¹⁷ This finding suggests that HTLV-1 must have a mechanism of inhibiting viral gene transcription *in vivo*. An HDAC inhibitor, valproate, induces *tax* gene transcription. Administration of valproate to patients with HAM/TSP reduces the provirus load,²¹⁹ suggesting that recovery of Tax expression induces CTLs to kill infected cells. Thus, Tax expression is suppressed by an epigenetic mechanism *in vivo*, and recovery of Tax expression induces a CTL response. Indeed, quantification of *in vivo* lymphocyte dynamics shows that CD4+CD45RO+ and CD8+CD45RO+ T-cell proliferation is elevated in HTLV-1-infected individuals. The *in vivo* proliferation of CD4+CD45RO+ T cells correlates with Tax expression,¹⁸ indicating the dynamics of HTLV-1-infected CD4+ T cells and reacting CD8+ T cells *in vivo*.

HLA-A*02 and C*08 are associated with a reduced risk of HAM/TSP and a decreased provirus load in asymptomatic carriers, whereas HLA-B*54 is linked with an increased risk of HAM/TSP and an increased provirus load in HAM/TSP patients.¹⁶¹ Furthermore, a killer cell immunoglobulin-like receptor (KIR), KIR2DL2, potentiates protective and detrimental effects of these human leukocyte antigen (HLA) class I-mediated immunity.³¹³ This study showed that the protective effect of HBZ peptides by HLA class I molecules is enhanced by KIR2DL2, suggesting that HBZ is also a critical target proteins for CTLs. The *HBZ* gene, which supports proliferation of HTLV-1-infected cells, has been found to be continuously expressed *in vivo*.³⁰⁸ Tax is highly immunogenic,^{158,178} whereas HBZ shows weak immunogenicity.¹²⁹ It has been reported that CTLs against HBZ protein determine the provirus load in HTLV-1-infected individuals,²²²

whereas CTLs against Tax are associated with inflammatory conditions.¹²⁹ Thus, the immune responses to these proteins might affect provirus load and disease status.

Viruses that cause chronic infection must evade the host immune system to enable persistent replication or proliferation. HTLV-1 appears to have evolved a strategy for allowing infected cells to evade the host immune response. One component of this strategy is the HTLV-1 accessory protein p12, which physically interacts with the free human MHC class I heavy chain and induces its degradation.¹⁷² Suppression of cell surface MHC class I expression facilitates the escape of HTLV-1-infected cells from destruction by the host immune system. A second component of this strategy is HBZ, which induces the expression of Foxp3 in infected T cells and increases the population of Treg cells *in vivo*.³⁰⁹ Indeed, in HTLV-1-infected individuals, provirus levels are disproportionately high in the Treg subpopulation.³⁶⁹ An increase in the number of Treg cells likely suppresses the host immune response, which would enable more infected cells to survive *in vivo*.

Immunodeficient State and Diseases

The host immune system controls the dynamics of HTLV-1 infection and the development of disease. This idea is supported by the clinical observations that ATL occurs fairly commonly in immunocompromised hosts. Among 24 patients with posttransplantation lymphoproliferative disorders (PT-LPD) after renal transplantation in Japan, five ATL cases have been reported.¹⁴² HTLV-1 was likely transmitted via blood transfusion during hemodialysis. It is likely that the immunodeficient state of recipients promotes the onset of ATL. Furthermore, of eight HTLV-1 carriers who received living-donor liver transplants and subsequent immunosuppressive treatment, three developed ATL.¹⁸⁵ Collectively, these findings indicate that the host immune system commonly suppresses the development of ATL, whereas an impaired immune system may allow HTLV-1-infected cells to transform into ATL cells.

HTLV-1 carriers show mild impairments of cell-mediated immunity. *Strongyloides stercoralis* infection, for example, is more severe in HTLV-1 carriers.³⁸⁷ The impairment of cell-mediated immunity is more profound in ATL patients, who frequently succumb to opportunistic infections with various pathogens, including fungus, cytomegalovirus, *Pneumocystis jirovecii*, and mycobacterium.³⁵⁵ One possible reason for this immune deficiency is that HTLV-1 infection increases the population Treg cells, because HBZ induces the expression of Foxp3.³⁰⁹

Provirus Sequences In Vivo

Analysis of viral gene transcription in ATL cells showed that in approximately 60% of cases, ATL cells did not express Tax.³⁵⁶ Three mechanisms by which Tax expression was disrupted were identified: (a) deletion of the 5' LTR,^{239,358} (b) DNA methylation of the 5' LTR,^{198,362} and (c) genetic changes of the *tax* gene (nonsense mutations, deletion, and insertion).^{73,84} In all cases, the pX region and the 3' LTR remained intact, suggesting the importance of the *HBZ* gene.

Analysis of whole HTLV-1 proviruses in ATL cells shows that all viral genes can contain nonsense mutations except the *HBZ* gene.⁷³ Most nonsense mutations were generated in a tryptophan codon (TGG) by G-to-A mutation (TGG to TGA, or TGG to TAG). The sequences of these G-to-A mutations in HTLV-1 proviruses correspond to the target sequences of

APOBEC3G.⁷³ APOBEC3G is a host factor that generates G-to-A mutations during reverse transcription. In the case of HIV, an accessory protein, Vif, promotes the degradation of APOBEC3G, which enables HIV to escape fatal nonsense mutations. HTLV-1 does not encode an accessory gene that counteracts APOBEC3G. It has been reported that the gag region of HTLV-1 suppresses the incorporation of APOBEC3G into the virion.⁶² However, this inhibitory activity is not strong enough to completely suppress all G-to-A mutations.³⁰⁶ If nonsense mutations are generated in viral genes that are not essential to proliferation, HTLV-1-infected cells can still proliferate and transform to leukemic cells. This result indicates that nonsense mutations of all viral genes except the *HBZ* gene can be generated before integration and ATL can still ensue, suggesting that *HBZ* is an unexpectedly essential gene for leukemogenesis.

EPIDEMIOLOGY

Age

HTLV-1 is transmitted via three major routes: breast-feeding, sexual transmission, and parenteral transmission. Seropositivity of infected babies was established by the age of 2 years, indicating that transmission via breast-feeding continued until that age.¹⁰ In adults, HTLV-1 seroprevalence rises according to age, and the seropositivity of females is higher than that of males.³⁶ The reason is that sexual transmission of this virus is more efficient from male to female than from female to male.^{143,340} It is of note that sexual transmission has occurred even in old HTLV-1 discordant couples, a fact that can account for the increase in seropositivity in the elder population. The average age of ATL patients was 63 years in Japan, which is 15 years older than the average age of ATL patients in the Caribbean Islands,³⁵⁵ suggesting that genetic background and/or environmental factors influence development of ATL. The mean age of onset of HAM/STP patients was 43 years.²⁸⁰ In addition, HAM/TSP rapidly develops in some cases after infection. These findings suggest that onset of HAM/TSP does not need a long latent period compared with ATL.

Morbidity/Mortality

HTLV-1 establishes persistent infection. The cumulative risks of ATL among HTLV-1 carriers in Japan is estimated to be about 6.6% for men and 2.1% for women, indicating that most HTLV-1 carriers remain asymptomatic throughout their lives.¹⁴ The incidence of HAM/TSP is estimated to be about 0.1% of these HTLV-1 carriers in Japan. There are geographical differences in the incidences of these HTLV-1-associated diseases.¹³⁶ The incidence of HAM/TSP is approximately seven times higher in Jamaican subjects compared with the Japanese population, whereas that of ATL is four times lower in Jamaicans. Differences in immune markers between Japanese and Jamaican HTLV-1-infected individuals have been reported: higher titers of antibody and more activated T-cell immunity in Jamaicans compared to Japanese individuals.³⁵ Differences in HTLV-1-related host immunity might be linked to the differences in ATL and HAM/TSP risks for these populations.

Origin and Spread of Epidemics

HTLV-1 is a member of the deltaretroviruses, which include HTLV-2, bovine leukemia virus, and simian T-cell leukemia

virus (STLV). HTLV and STLV are thought to originate from common ancestors and share molecular, virological, and epidemiological features. Therefore, they have been designated primate T-cell leukemia viruses (PTLVs). Phylogenetic analyses have revealed that HTLV-1c first diverged from STLV around $50,000 \pm 10,000$ years ago, whereas the spread of HTLV-1 in Africa is estimated to have occurred at least $27,300 \pm 8,200$ years ago. Subsequently, HTLV-1a, which is the most common subtype in Japan, diverged from the African strain $12,300 \pm 4,900$ years ago.³⁸³ Thus, these viruses have had a long history with humans after the initial interspecies transmission. In contrast, HIV-1 is thought to originate from simian immunodeficiency virus in chimpanzees (SIV_{CPZ}),⁸⁶ and the interspecies transmission to humans is estimated to have occurred about 100 years ago.⁴⁰¹ Recently, new retroviruses have been identified in bush meat hunters in Central Africa. HTLV-3 has been found in asymptomatic carriers in Cameroon.^{44,400} HTLV-3 shares high homology with its simian counterpart, STLV-3, which was detected in monkeys in Africa. The genome organization of HTLV-3 is similar to HTLV-1.²²⁵ No diseases have been reported to be associated with HTLV-3.

Prevalence and Seroepidemiology

It is estimated that 10 million to 20 million people live with HTLV-1 worldwide.²⁹⁷ Areas endemic for this virus are southwestern Japan, the Caribbean basins, Central and West Africa, and South America. In addition, epidemiological studies of HTLV-1 have revealed high seroprevalence rates in Melanesia, Papua New Guinea, and the Solomon Islands, as well as among Australian aborigines.³⁶ In Japan, approximately 1.08 million individuals were estimated to be infected with HTLV-1 in 2009, and among them, 1,000 carriers develop ATL each year.

Genetic Diversity of Virus

Unlike HIV, HTLV-1 has low sequence variability.⁹² Because reverse transcriptase is an error-prone DNA replication enzyme,

viral replication generates mutations in the proviral sequences. In the case of HTLV-1, however, the virus induces infected cells to proliferate rather than producing virions; as a result, sequence variations are rare compared with HIV. Nevertheless, several subtypes of HTLV-1 have been identified. According to previous reports, HTLV-1 strains include the six following subtypes: the cosmopolitan HTLV-1a subtype;²³⁷ the Central African subtypes HTLV-1b,^{109,386} HTLV-1d,²²⁶ HTLV-1e,³³⁷ and HTLV-1f;³⁰⁴ and the Australo-Melanesian subtype HTLV-1c.^{94,321} These subtypes are closely linked with interspecies transmission and human migration events.

CLINICAL FEATURES

After infection with HTLV-1, HTLV-1 provirus load remains relatively constant within an individual but differs among infected individuals. In other words, different individuals have different provirus load “set points.” Most individuals remain asymptomatic during their entire lives, whereas a small fraction of carriers develop HTLV-1–associated diseases (Fig. 48.11). HTLV-1 causes both a neoplastic disease, ATL, and inflammatory diseases, including HAM/TSP, uveitis, alveolitis, and infective dermatitis. In addition, HTLV-1 infection also suppresses cell-mediated immunity.³⁹⁷ Provirus load is a critical factor for pathogenesis of these disorders.

Adult T-Cell Leukemia

ATL develops predominantly in males (the male to female ratio is 1.5:1), whose age at onset ranges from 25 to 94 years, with a median age of 63 years in Japan. The predominant physical findings are peripheral lymph node enlargement (72% of cases), hepatomegaly (47%), splenomegaly (25%), and skin lesions (53%).³⁵⁵ ATL cells infiltrate into various organs/tissues, including skin, liver, lung, the gastrointestinal tract, the central nervous system, and bone. Various skin lesions, such

FIGURE 48.11. The natural course of HTLV-1 infection. After transmission of HTLV-1, infected cells proliferate owing to the actions of Tax and HBZ. The growth of HTLV-1–infected cells is suppressed by cytotoxic T lymphocytes *in vivo*. The number of HTLV-1 infected cells is thus determined by balance between viral gene expression and host immune system. About 5% of HTLV carriers develop adult T-cell leukemia after a long latent period. A smaller fraction of carriers present with inflammatory diseases, such as HTLV-1–associated myelopathy/tropical spastic paraparesis (HAM/TSP), uveitis, or alveolitis. Most carriers remain asymptomatic.

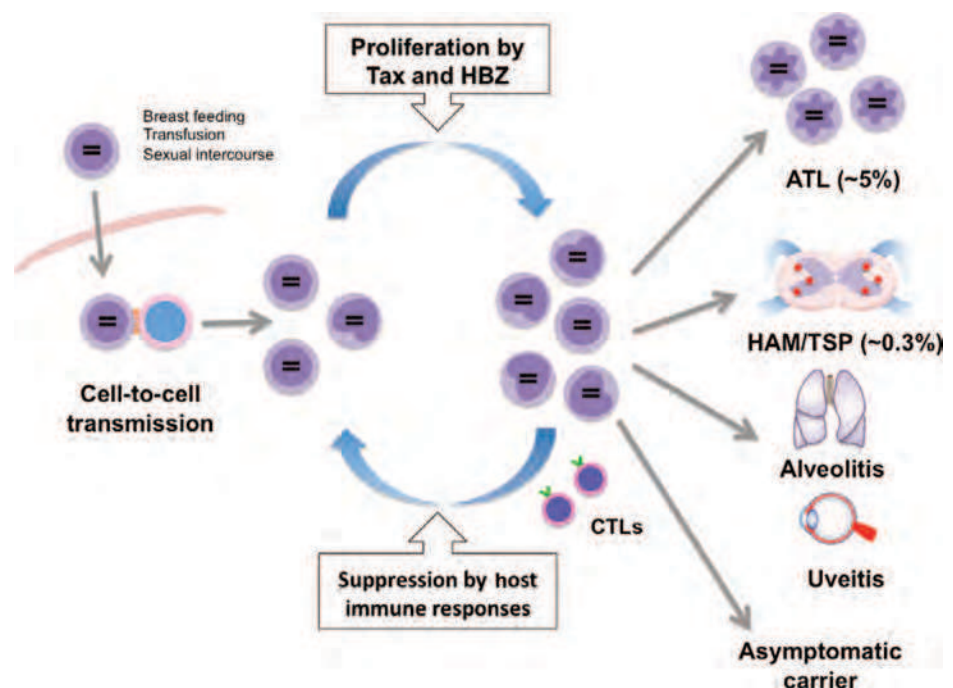

FIGURE 48.12. Skin lesion of an adult T-cell leukemia (ATL) patient. ATL cells frequently involve skin and form various lesions. In this patient, ATL cells form a tumorous lesion.

as papules, erythema, and nodules are frequently observed in ATL patients (Fig. 48.12). ATL cells densely infiltrate the dermis and epidermis, forming Pautrier's microabscesses in the epidermis (Fig. 48.13).

ATL cells in the peripheral blood have indented or lobulated nuclei (Fig. 48.14). Anemia and thrombocytopenia are rare because involvement of bone marrow is not severe. The typical surface phenotype of ATL cells is CD4+CD8-CD25+,

FIGURE 48.13. Skin involvement of adult T-cell leukemia (ATL). **A:** ATL cells infiltrate into epidermis and form Pautrier's microabscesses (arrows). **B:** CD4+ cells are identified by the immunohistochemical staining.

FIGURE 48.14. Adult T-cell leukemia (ATL) cells in the peripheral blood. ATL cells in an acute ATL case show specific morphology.

FIGURE 48.15. Lymph node lesion of an adult T-cell leukemia (ATL) patient. A: Histological analysis (hematoxylin-eosin staining) shows monotonous proliferation of ATL cells. **B:** Immunohistochemical analysis shows that ATL cells are FoxP3 positive.

which is similar to that of activated T cells and Treg cells. Foxp3 is expressed in ATL cells in two-thirds of cases (Fig. 48.15),¹⁸⁰ indicating that such ATL cells are derived from Treg cells. ATL cells express CD25 (IL-2R alpha chain) on their surfaces and secrete its soluble form. Therefore, levels of soluble IL-2Rs are elevated in the sera of patients with ATL, with the levels of soluble IL-2R being correlated with the tumor mass and clinical course.⁴¹⁴ ATL cells elaborate various cytokines that can affect the immune response and influence the pathophysiology of ATL. For example, eosinophilia, caused by elevated IL-5 levels, is frequently observed in patients with ATL.

Hypercalcemia is a complication in about 70% of ATL patients at some point during the clinical course of the disease, particularly during the aggressive stage.¹⁹⁶ Pathologic studies of ATL patients with hypercalcemia have shown that high serum Ca^{2+} levels are attributable to an increased number of osteoclasts (OCL) and accelerated bone resorption (Fig. 48.16).

FIGURE 48.16. Increased number of osteoclasts in a hypercalcemic adult T-cell leukemia patient. In a hypercalcemic patient, the number of osteoclasts increases in the bone and accelerates bone resorption.

During differentiation of OCLs, precursor cells sequentially express c-Fms (the receptor for M-CSF) followed by receptor activator nuclear factor κB (RANK).¹² M-CSF and RANK ligand (RANKL) have been shown to be critical factors for the differentiation of OCLs and are physiologically produced by stromal cells and osteoblasts. ATL cells from patients with hypercalcemia have high RANKL transcript levels and induce the differentiation of hematopoietic stem cells into OCLs *in vitro* in the presence of M-CSF.²⁶⁷ In addition, parathyroid hormone-related protein (PTH-rP) elaborated from ATL cells activates OCLs and promotes bone resorption.³⁹⁴

HTLV-1–Associated Myelopathy/Tropical Spastic Paraparesis

HAM/TSP is characterized by a slow progressive spastic paraparesis, urinary dysfunction, and sensory disturbances.²⁸⁰ HAM/TSP patients also often have other organ disorders such as leukoencephalopathy (69%), abnormal findings on chest x-ray (50%), Sjögren syndrome (25%), and arthropathy (17%).²⁵⁶ In contrast to ATL, HAM/TSP develops predominantly in females (the male to female ratio is 1:2.9).

Pathologic studies of HAM/TSP patients demonstrated the severe involvement of the thoracic spinal cord, in which T cells cause perivascular cuffing and infiltrate into the parenchyma.²⁸⁰ In HAM/TSP, the provirus load is high compared with asymptomatic carriers,²⁵⁴ and more HTLV-1–infected CD4+ T cells infiltrate into the spinal cord.^{46,233,246} The number of HTLV-1–specific HLA class I restricted CD8+ T cells is also increased in HAM/TSP patients.¹⁵⁸ Among viral antigens, Tax has a dominant epitope that is recognized by CTLs.^{103,178} Tax-reacting CD8+ T cells also migrate into the spinal cord along with HTLV-1–infected CD4+ T cells.³⁷⁷ These HTLV-1–infected cells and reacting CTLs produce proinflammatory cytokines (tumor necrosis factor-alpha [TNF- α], IFN- γ , IL-1 β), leading to demyelination and axonal damage.

HTLV-1 Uveitis

HTLV-1 infection induces uveitis, which is an inflammatory disorder that affects the intraocular tissues. The most characteristic ocular findings of HTLV-1 uveitis were vitreous opacities

associated with mild iritis and mild retinal vasculitis. This type of uveitis is classified as intermediate uveitis, because the intermediate part of the eyeball is affected by the inflammation.²⁴² Infiltrating HTLV-1–infected cells are implicated in the pathogenesis of this uveitis. Patients with HTLV-1 uveitis are treated with topical or systemic corticosteroids.

Infective Dermatitis

Infective dermatitis, a severe, chronic, relapsing dermatitis first described in Jamaican children, was found to be associated with HTLV-1 infection.²⁰⁴ Infective dermatitis is characterized by a severe exudative dermatitis with crusting of the scalp, neck, external ears, axillae, and groin. In the skin region, *Staphylococcus aureus* or beta-hemolytic *Streptococcus* infection is detected. Oral trimethoprim-sulfamethoxazole is the treatment of choice because of low cost and effectiveness.²²⁴ Patients with infective dermatitis tend to have an elevated provirus load. Infective dermatitis has been reported prior to the development of ATL and HAM/TSP; therefore, infective dermatitis is implicated as an indicator for other HTLV-1–associated diseases.

DIAGNOSIS

HTLV-1 infection can be diagnosed by the presence of antibody to HTLV-1. The presence of serum antibodies against HTLV-1 can be demonstrated by enzyme-linked immunosorbent, particle agglutination, indirect immunofluorescence, and Western blot assays. Provirus load, which represents the number of infected cells, is measured by real-time PCR. In HTLV-1–infected individuals, provirus load ranges from less than 0.01% up to more than 50% (the percentage is shown as provirus positive cells as if a cell contains one copy of HTLV-1 provirus). High provirus load is thought to be associated with HTLV-1–associated diseases and is a risk factor for ATL.

The diagnostic criteria for ATL have been defined as follows: (a) histologically and/or cytologically proven lymphoid malignancy with T-cell surface antigens; (b) abnormal T cells present in the peripheral blood (except for lymphoma-type ATL)—these abnormal T lymphocytes can include not only typical ATL cells, the so-called flower cells, but also the small and mature T lymphocytes with incised or lobulated nuclei that are characteristic of the chronic or smoldering type of ATL; (c) antibody to HTLV-1 present in the serum at diagnosis; and (d) demonstration of monoclonal integration of HTLV-1 provirus by the Southern blot method.

PREVENTION AND CONTROL

Treatment

As expected, reverse transcriptase inhibitors (RTIs) can suppress replication of HTLV-1 *in vitro*, although the efficacies of various RTIs against HTLV-1 are different from those against HIV-1.¹³⁰ RTIs can also block HTLV-1 infection if they are administered at the time of HTLV-1 exposure.²³⁴ However, RTIs cannot suppress HTLV-1 infection if they are administered 1 week later.²⁴⁰ This finding suggests that clonal proliferation of infected cells is predominant after the initial *in vivo* spread of HTLV-1. It is consistent with the observation

that RTIs do not change provirus load in patients with HAM/TSP.³⁶⁴ Thus, the clinical use of inhibitors against HTLV-1 replication is limited to preventative administration for accidental exposure to HTLV-1–positive blood.

HTLV-1–associated diseases, ATL and HAM/TSP, must be treated. ATL is a poorly treatable neoplastic disease owing to its resistance to anticancer drugs and the complication of immunodeficiency. Patients with acute or lymphoma-type ATL are usually treated with combination chemotherapy. With the most commonly used combination chemotherapy in Japan (VCAP-AMP-VECP therapy: vincristine, cyclophosphamide, doxorubicin, and prednisone [VCAP], doxorubicin, ranimustine, and prednisone [AMP], and vindesine, etoposide, carboplatin, and prednisone [VECP]),⁴⁰⁶ 81% of the 93 eligible patients responded, with 33 patients obtaining complete response (35.5%) and 42 obtaining partial response (45.2%). The median survival time of patients was 13 months. This protocol was found to be superior to biweekly CHOP (cyclophosphamide, hydroxydaunorubicin, vincristine [Oncovin], and prednisone) therapy.³⁷⁴

The major impediments in therapy for ATL patients are the drug resistance of ATL cells to chemotherapeutic agents and the profound immunodeficient state of patients.³²⁴ The immunodeficiency of ATL patients may be caused by the immunosuppressive function of ATL cells, because they likely arise from Treg cells¹⁸⁰ and can produce immunosuppressive cytokines.²⁶⁵ The immunodeficiency of ATL patients leads to complications by various opportunistic fungal, viral, and bacterial infections, which worsens the prognosis.³⁵⁵

Successful allogeneic bone marrow transplantation was reported for an acute ATL patient in 1996.^{42,368} Furthermore, allogeneic stem cell transplantation (alloSCT) has been reported to be effective in ATL patients.³⁸⁰ However, because ATL patients are usually older (63 years in Japan), the intense conditioning (whole body irradiation, anticancer drugs) is too toxic. Patients treated with alloSCT with reduced-intensity conditioning (RIST), in which reduced dose of anticancer drugs and immunosuppressive agents are used, had overall survival at 3 years of 36%.³⁶³ These studies showed that 30% to 40% of ATL patients became long-term survivors with either conventional alloSCT or RIST.²⁷⁶ HTLV-1 provirus load decreased remarkably in many patients who received alloSCT,²⁷⁷ suggesting that cell-mediated immunity to HTLV-1 was enhanced in these patients—an observation that might account for the efficacy of this therapy. ATL cells express high levels of cell surface Fas antigen and are susceptible to Fas-mediated signaling.^{357,416} These findings suggest that ATL cells are vulnerable to CTLs, which accounts for the good therapeutic responses. In individuals who received alloSCT, CTLs to Tax peptides were activated in the recipients and provirus load became profoundly suppressed, suggesting a role of anti-HTLV-1 immune responses in the efficacious outcome.¹¹⁹ Nevertheless, further study is needed to determine whether CTLs to Tax indeed play a critical role for the efficacy of stem cell transplantation therapy.

A humanized monoclonal antibody, rituximab, dramatically improved the prognosis of B-cell lymphoma patients. Similarly, monoclonal antibodies to CD25,²⁸⁹ CD2,⁴²⁸ CD52,⁴²⁷ and CCR4¹⁵¹ have been shown to suppress ATL cells *in vivo*. KW-0761, a defucosylated humanized anti-CCR4 antibody, has shown to be effective in some ATL patients.⁴⁰⁸ Among 15

patients treated with KW-0761, 5 patients achieved positive objective responses: two complete and three partial responses. These antibody therapies are potentially beneficial for ATL patients because they avoid the adverse effects of chemotherapeutic agents on the host. In addition, it has been reported that a proteasome inhibitor, bortezomib, suppresses tumor formation by ATL cells *in vivo*.^{236,307,359} NF- κ B inhibitors also effectively induced apoptosis of ATL cells, because NF- κ B is highly activated in ATL cells.^{342,393} These findings suggest the potential efficacy of these compounds for ATL patients.

Previous studies reported that the prognosis of patients with aggressive subtypes of ATL (acute and lymphoma types) was less than 1 year, whereas that of indolent types (chronic and smoldering types) was much longer.³²⁵ It was recently reported that the mean survival time of patients with the indolent subtypes of ATL was only 4.1 years,³⁵³ indicating that the prognosis of indolent ATL is poorer than previously thought. Therapy using IFN- α combined with zidovudine has been reported to be highly effective for these indolent ATL patients.²⁸ However, viral replication has not been demonstrated in ATL cells. Instead, many nonsense mutations, deletion, and insertions of HTLV-1 provirus were reported in ATL cells.^{73,356} Taken together, these data suggest that IFN- α combined with zidovudine may suppress the growth of ATL cells without any effects on viral replication.

For treatment of patients with HAM/TSP, oral prednisone or injection of IFN- α provides a transient beneficial efficacy.²⁸⁰

Vaccines

The passive transfer of immunoglobulin derived from HTLV-1-infected individuals could block HTLV-1 infection,^{245,310} suggesting that a vaccine to HTLV-1 is capable of inhibiting its transmission. Indeed, immunization with peptide derived from envelope protein²⁵⁷ and vaccines expressing envelope protein³²² can block transmission of HTLV-1 in rabbits and monkeys. Taken together, these findings clearly show that a preventive vaccine for HTLV-1 is possible, a situation quite different from that with HIV-1.

Tax might be a target for a therapeutic vaccine owing to its high immunogenicity. In a rat model, a Tax peptide-based vaccine inhibited the growth of a Tax expressing rat T-cell line *in vivo*.¹¹⁵ However, the fact that Tax expression is frequently lost in ATL cells points to the limitation of Tax for therapeutic vaccine of ATL.

Prevention

HTLV-1 is transmitted via three routes, all of which can be preventable. Mother-to-infant transmission can be reduced by bottle-feeding or freeze-thaw processing of breast milk,⁹ which destroys the infected cells in the breast milk. However, HTLV-1 transmission still occurs in about 5% of infants who do not drink breast milk, indicating the presence of the route other than breast milk for the transmission.³⁵¹ Transmission risk by breast-feeding increased according to HLA concordance between mother and child.³⁴ This finding suggests that immunological responses influence the transmission from mother to child. Blood screening almost completely prevents viral transmission by blood transfusion.¹⁴⁸ RTIs should be useful for preventing *de novo* infection by accidental exposure to contaminated blood, although any clinical evidence has not yet been reported.

PERSPECTIVES

Since the discovery of HTLV-1, extensive studies have revealed a complex network of interactions between viral genes and host factors. This network controls the expression of viral genes and facilitates persistent infection by allowing evasion of the host immune response and promoting the proliferation of infected cells. However, many enigmas remain, including how HTLV-1 drives ATL cells and infected cells to proliferate in the absence of Tax expression, and whether the HTLV-1 provirus is necessary in ATL cells. These long-standing questions might be answered by the discovery of an antisense transcript of HTLV-1, the *HBZ* gene. Recent studies show complex interactions between HBZ and Tax, which likely regulate ATL cells and infected cells to allow their sustained proliferation in the presence of host immune pressure. The complex relationship between Tax and HBZ needs to be further clarified.

A long latent period is necessary for development of ATL, indicating that the accumulation of alterations in the host genome is needed for its onset. The detailed mechanisms of leukemogenesis should be studied further from both viral and cellular perspectives.

Another important issue is the need for better therapies for HTLV-1-associated diseases. Previously, the prognosis of ATL patients was very poor. New therapies, including stem cell transplantation and zidovudine/IFN- α , have improved the prognosis of ATL patients. However, preventive therapy and antiviral therapy are not yet available for HTLV-1. In addition, good therapeutic strategies are needed for treating HAM/TSP, which is an unrelenting debilitating disease.

INTRODUCTION

In the late 1970s and early 1980s, previously healthy patients with symptoms of immunologic dysfunction sought advice and treatment from physicians in the United States and Europe. This new and unusual syndrome was characterized by generalized lymphadenopathy, opportunistic infections (typically *Pneumocystis carinii* pneumonia, cytomegalovirus-associated retinitis, and cryptococcal meningitis), and a variety of unusual cancers (non-Hodgkin's lymphoma and Kaposi's sarcoma). A common accompanying laboratory finding in affected individuals was marked depletion of the CD4+ T-lymphocyte subset in the peripheral blood. The disease was first brought to the attention of the general medical community in June 1981 when

the Centers for Disease Control and Prevention described five California men with severe immunodeficiency in the *Morbidity and Mortality Weekly Report*⁵²⁹ (Fig. 49.1). This notification was followed by several reports describing male homosexuals and intravenous drug users with impaired immune systems characterized by T lymphocytes that responded poorly to antigen and mitogen stimulation in functional assays. Within several months, it became clear that a similar immunodeficiency syndrome was also affecting other groups, including hemophiliacs, blood transfusion recipients, recent Haitian immigrants, and, most significantly, sexual partners or children of members of the various risk groups.

The emerging epidemiologic pattern suggested that the new disease was transmitted by a novel pathogen in contaminated blood or following sexual intercourse with an affected individual. Between late 1981 and early 1983, a variety of microorganisms were proposed as possible causes of acquired immunodeficiency syndrome, or AIDS, as the disease was soon called. In the spring of 1983, Montagnier and colleagues³² at the Pasteur Institute reported the isolation of an agent from the lymph nodes of an asymptomatic individual who presented with generalized lymphadenopathy of unknown origin. During its replication in cultured cells, the lymphadenopathy-associated virus, or LAV as it was named, released high titers of progeny virions that contained magnesium-dependent reverse transcriptase (RT) activity and exhibited electron microscopic (EM) features typical of retroviruses. However, unlike the commonly studied retroviruses such as the avian leukosis viruses (ALVs) and the murine and feline leukemia viruses (MLVs and FeLVs), LAV was highly cytopathic in human peripheral blood mononuclear cells (PBMCs), specifically killing CD4+ T lymphocytes in cell cultures.⁵³² Gallo and colleagues^{608,658} at the National Institutes of Health subsequently reported the isolation of a retrovirus from an AIDS patient, which they named human T-cell leukemia virus type III (HTLV-III) to distinguish it from the non-cytopathic HTLV-1, and obtained the first serologic evidence linking exposure to LAV-like retroviruses and immunodeficient individuals from the various groups at risk. The new retrovirus, associated with AIDS in the United States, Europe, and central Africa and exhibiting morphologic and genetic characteristics typical of the lentivirus genus, was named human immunodeficiency virus, or HIV¹⁴⁰ (and subsequently HIV-1). In 1986, a related but immunologically distinct human retrovirus (now called HIV-2) was recovered from individuals residing in several West African countries such as Senegal, the Ivory Coast, and Guinea-Bissau.¹³⁹ Prior to the discovery and use of highly active

MILESTONES IN HIV-1 RESEARCH

antiretroviral therapy (HAART), the risk of death for HIV-1–infected persons was 40-fold higher than the mortality in the general population, whereas HIV-2–infected individuals had a 2- to 5-fold higher risk.^{57,293,614}

CLASSIFICATION OF HUMAN IMMUNODEFICIENCY VIRUSES

One of the first features the Pasteur Institute group noted about HIV-1 was its particle-associated RT activity, a property that placed the new agent in the *Retroviridae* family. This feature was consistent with EM analyses of particles released from infected cell cultures, which revealed 100- to 120-nm enveloped virions, similar in size and morphology to previously studied retroviruses. The mature HIV-1 particles contained a cone-shaped cylindrical core reminiscent of that previously described for visna virus (Fig. 49.2A).²⁶⁹ The cloning and sequencing of proviral DNA, initially purified from productively infected cultures of PBMC/T-cell leukemia lines (T-cell lines), indicated that HIV-1 not only possessed a genomic organization related to other replication-competent retroviruses but also was placed taxonomically in the *Lentivirus* genus.^{620,786} This relationship

is shown diagrammatically in Figure 47.2 of Chapter 47. As their name suggests, lentiviruses were known to cause slow, unremitting disease in sheep, goats, and horses and to target various lineages of hematopoietic cells, particularly monocytes/macrophages and lymphocytes.

After the isolation, molecular cloning, and initial classification of HIV-1, several genetically distinct primate lentiviruses were subsequently discovered and their phylogenetic relationships to HIV-1 were determined. For example, viruses isolated from captive macaques or feral monkey species in Africa were shown to possess particle morphologies and genomic organizations similar to those of HIV-1 (described in Chapter 51). Because inoculation of Asian macaque species, such as rhesus monkeys, with these newly discovered agents recovered from African monkeys induced an AIDS-like illness,¹⁵⁹ these viruses were named simian immunodeficiency virus (SIV) to distinguish them from the human viruses, HIV-1 and HIV-2. The phylogenetic relationships of the two human lentiviruses are depicted in Figure 49.3; the detailed genetic interrelationships of all members of the primate lentivirus genus are presented in Figure 52.1B of Chapter 52. HIV-2 is more closely related to SIV_{sm},³²⁰ a virus indigenous to African sooty mangabey monkeys, than to HIV-1. Because of the close contact between

FIGURE 49.2. Primate lentiviruses have a distinct morphology and can induce syncytia during productive infections.

A: Electron micrograph showing a single human immunodeficiency virus 1 (HIV-1) particle in the process of budding from infected cultured human peripheral blood mononuclear cells (PBMCs) and several mature virions containing the characteristic conical or bullet-shaped core ($\times 100,000$). (**A** courtesy of Dr. Jan Orenstein.) **B:** Typical ballooning syncytia induced by primate lentiviruses as visualized by inverted light microscopy at the time of peak virus production.

humans and monkeys, which are hunted for food or kept as pets in West Africa, it is currently thought that HIV-2 represents a zoonotic transmission of SIV_{sm} from monkeys to humans.²⁵³

Based on previously studied replication-competent retroviruses (e.g., MLV, ALV, and HTLV), it was originally thought that HIV-1 would be genetically homogeneous. However, as proviral DNAs corresponding to HIV-1 isolates from Europe, North America, and Africa, became available and were compared to one another, their extensive genetic heterogeneity became apparent.⁴⁴ No two HIV-1 isolates were identical. When subjected to nucleotide sequence analysis, even HIV-1

samples recovered from a single individual exhibited significant heterology. Although nucleotide changes were distributed throughout the HIV-1 genome, the greatest variability occurred in the gene encoding the envelope (Env) glycoprotein, gp160. The term *quasispecies* was subsequently coined to describe the pool of diverse and changing populations of virus present in an HIV-1-infected individual.⁵²¹ Nonetheless, a highly conserved immunodominant domain, located within gp41 Env-coding sequences, was found to elicit antibodies in exposed individuals, reactive with HIV-1 samples of diverse geographic origin.²⁶³ Although not neutralizing, these antibodies could be used in enzyme-linked immunosorbent assay (ELISA) and immunoblotting assays to identify virus-infected persons.

Several factors contribute to the extraordinary genetic heterogeneity of HIV-1: (a) error-prone viral DNA synthesis during reverse transcription (1 to 2×10^{-5} mutations/nucleotide/replication cycle in tissue culture systems; 5×10^{-5} within a patient), (b) high recombination frequencies accompanying reverse transcription, (c) high levels of progeny virus production *in vivo* (10^9 particles/day; millions of replication cycles/year), and (d) large numbers of infected individuals.^{141,359,491,592,759} It has been estimated that within an HIV-1-infected person, viral genetic diversity increases by 1% per year from the founder virus strain during the early asymptomatic phase of the infection.⁶⁸⁹

The earliest phylogenetic analyses of HIV-1 isolates focused on samples from Europe, North America, and Africa;

FIGURE 49.3. Phylogenetic relationships of human immunodeficiency virus 1 (HIV-1) and HIV-2 based on identity of *pol* gene sequences. Simian immunodeficiency virus (SIV)_{cpz} and SIV_{sm} are nonhuman primate lentiviruses recovered from a chimpanzee and sooty mangabey monkey, respectively.

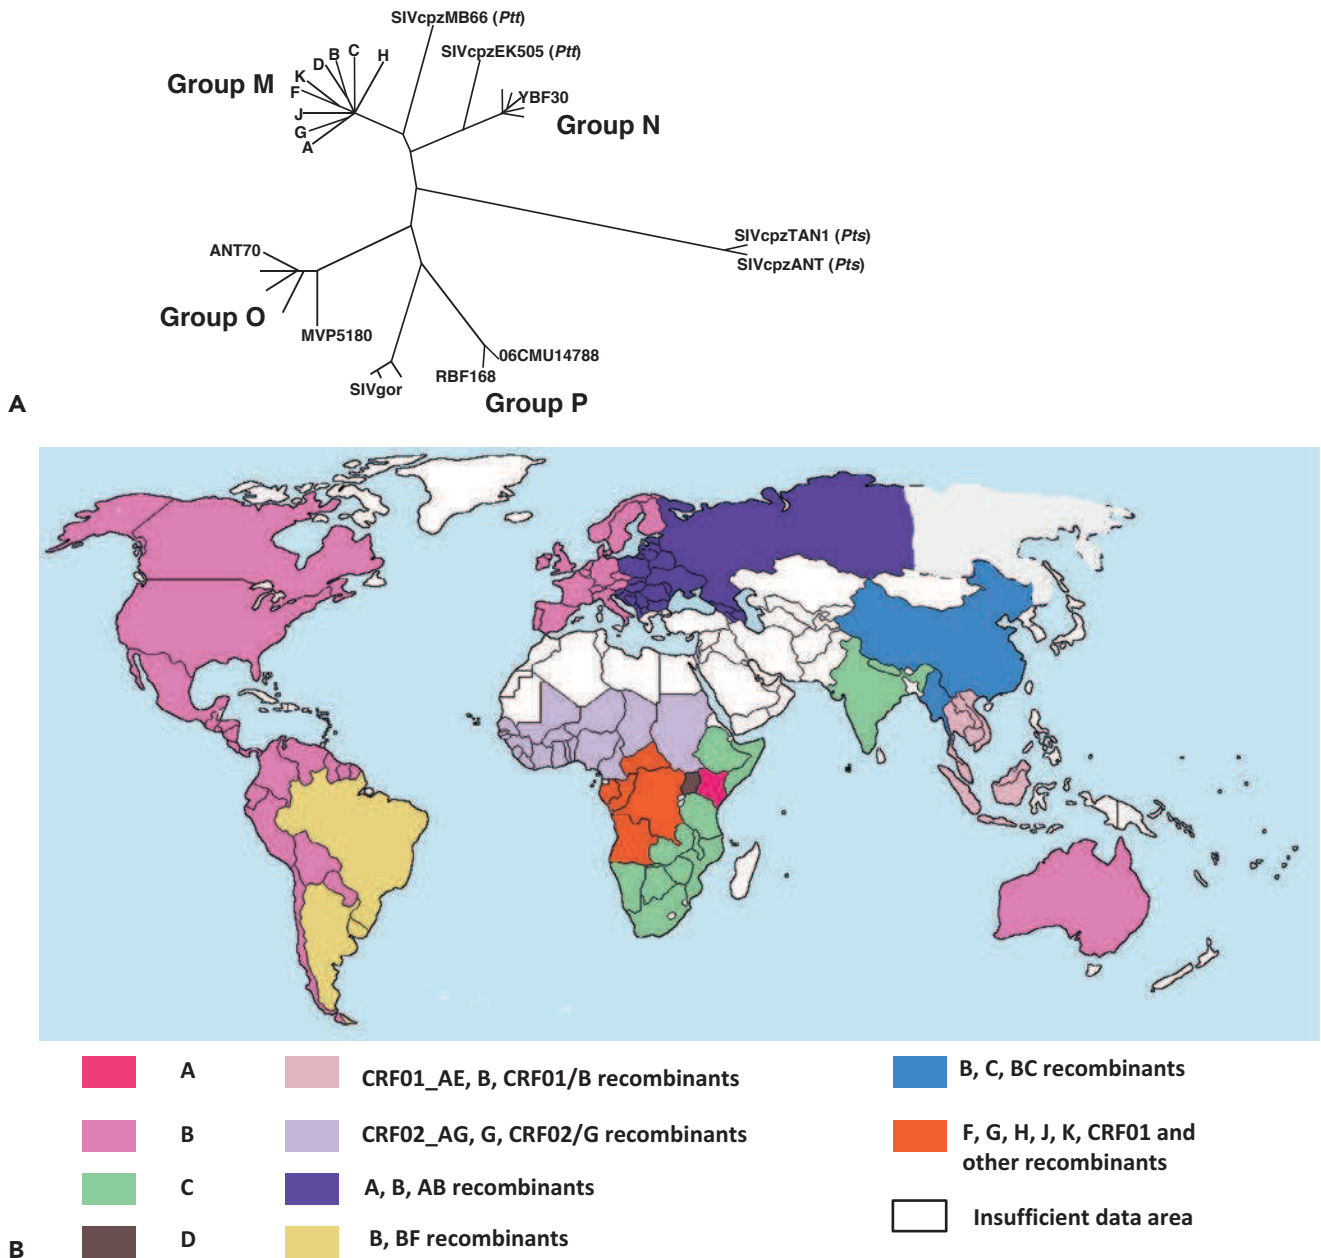

FIGURE 49.4. Human immunodeficiency virus 1 (HIV-1) genetic subtypes and their worldwide distribution. A: Phylogenetic relationships of HIV-1 groups M, N, O, and P with different simian immunodeficiency virus (SIV_{cpz} and SIV_{gor}) isolates. This maximum-likelihood tree is adapted from Foster JL, Denial SJ, Temple BR, et al. Mechanisms of HIV-1 Nef function and intracellular signaling. *J Neuroimmune Pharmacol* 2011;6:230–246 with permission. **B:** The global prevalence of HIV-1 subgroups with the predominant clades or circulating recombinant forms (CRFs) in each geographic region indicated. (Courtesy Dr. Sodsai Tovanabutra, U.S. Military HIV Research Program, Henry Jackson Foundation.)

discrete clusters of viruses were identified from these geographical regions. Distinct genetic subtypes or clades of HIV-1 were subsequently defined and classified into four groups: M (main), O (outlier), N (non-M, non-O), and P (Fig. 49.4A). The M group of HIV-1, which includes more than 98% of the global virus isolates, consists of nine clades or subgroups (A, B, C, D, F, G, H, J, and K) and 49 circulating recombinant forms (CRFs).^{462,511,588,632} HIV-1 group O isolates have been recovered from individuals living in Cameroon, Gabon, and

Equatorial Guinea; their genomes share approximately 65% identity with group M viruses.⁷⁴² Early in the epidemic, group O strains may have been responsible for more than 20% of HIV-1 infections in Cameroon but are presently associated with approximately only 1%.⁷⁷³ Group N HIV-1 strains have been identified in 13 infected Cameroonians and are detectable using currently available immunoassays. Very recently, HIV-1 isolates, identified in two Cameroonians, have been classified as members of the new HIV-1 group P.⁷⁶⁴

As shown in Figure 49.4A, the nine clades comprising group M HIV-1 isolates are phylogenetically equidistant from one another, with internucleotide distances ranging from 15% to 20% in the *gag* gene and 20% to 30% in *env*.⁶³² Within-clade distances range from 3% to 10% for *gag* and 5% to 12% for *env*; up to 10% sequence diversity in the *env* gene has been reported for a single infected person.⁴¹² All of the HIV-1 group M subtypes can be found in Africa (Fig. 49.4B). With the rapid spread of HIV-1 to southern Africa during the mid- to late 1990s, clade C viruses have become the dominant subtype and now account for nearly half of HIV-1 infections worldwide.⁵⁷⁷ Clade A viruses, the most common HIV-1 subtype in Africa early in the epidemic, currently represent about 12% of infections globally, and are present mainly in Eastern and Central African countries. Clade B viruses, the most intensively studied HIV-1 subtype, remain the most prevalent isolates in Europe, North America, and Australia.

High rates of genetic recombination, a hallmark of retroviruses, are generated as a consequence of a single cell being infected by genetically distinct viral strains and arise as a result of template switching between two different viral RNAs during the reverse transcription reaction (see section on Reverse Transcription). By 1995, it became apparent that a significant fraction of the global diversity of HIV-1 group M viruses included interclade CRFs, which arose by the intermixing of viruses co-circulating in a particular geographical locale. It is now appreciated that HIV-1 recombinants will be found in geographical areas such as Africa, South America, and Southeast Asia where multiple HIV-1 subtypes coexist and account for nearly 20% of circulating HIV-1 strains globally. Molecularly, the genomes of these CRFs resemble patchwork mosaics, with juxtaposed diverse HIV-1 subtype segments, reflecting the multiple crossover events contributing to their generation. Most HIV-1 recombinants have arisen in Africa and a majority contains segments originally derived from clade A viruses. Although an intergroup (groups M and O) recombinant virus has been described,⁵⁸⁸ no recombination between HIV-1 and HIV-2 has been reported, although mixed *in vivo* infections involving the latter are known to occur.²⁷⁹

A primate lentivirus designated SIV_{cpz}, with a genomic structure very similar to that of HIV-1, including its signature *vpu* gene, has been isolated from two chimpanzee subspecies, *Pan troglodytes troglodytes* (*ptt*) and *Pan troglodytes schweinfurthii* (*pts*). The prevalence of SIV_{cpz} recovered from *ptt* animals (SIV_{cpzPtt}) in the wild varies widely (0 to 35%) compared to the more even and higher distribution of SIVs infecting sooty mangabeys and African green monkeys. Phylogenetically, the SIV_{cpzPtt} strains are related to HIV-1 groups M and N but not to group O or SIV_{cpzPis} (Fig. 49.4A), and geographically separated chimpanzee populations carry distinct genetic lineages of SIV_{cpzPtt}.³⁸⁵ A prospective study of habituated chimpanzees in Tanzania, using noninvasive approaches to acquire fecal and urine specimens for antiviral antibody and nucleic acid assays, reported that SIV_{cpz}-infected animals experienced a 10- to 16-fold increased risk of death and virus-positive females had decreased fertility and lower infant survival than uninfected chimpanzees, indicating that these infections are pathogenic in the wild.³⁸⁴ It has been suggested that SIV_{cpzPtt} is the source of recently described SIV_{gor} lineages recovered from Western lowland gorillas.⁷⁴¹

It is now generally accepted that cross-species transmission to humans of SIV_{cpz} in Central Africa and SIV_{sm} in West

Africa gave rise to HIV-1 and HIV-2, respectively.^{252,253} Based on nucleotide substitutions over time, a common ancestor of HIV-1 group M has been proposed to have emerged in the 1920s,⁸¹³ whereas progenitors for HIV-2 groups A and B have been dated to the 1940s.⁴³⁴ The SIV_{cpz} strains giving rise to HIV-1 have been introduced into humans at least four times (as reflected in groups M, N, O, and P). It is thought that the source of HIV-1 group M, the cause of the worldwide AIDS epidemic, originated in *ptt* chimpanzees living in southeast Cameroon.³⁸⁵ Infected humans very likely migrated from there, via tributaries of the Congo River, to Kinshasa, Republic of the Congo, where HIV-1 transmission greatly accelerated. Of the numerous species-specific strains of SIV that have been identified in more than 40 different species of African monkeys (see Chapter 51), none are related to SIV_{cpz} across the entire viral genome. However, *Vpu*-coding sequences, unique to HIV-1, have been identified in the SIV isolated from the greater spot-nosed monkey (SIV_{gsn}),¹⁴⁹ and phylogenetic analyses indicate that SIV_{gsn} (in the *env* gene) and SIV_{rcm} (in the *gag* and *pol* genes) are the two SIVs most closely related to SIV_{cpz}. On the basis of these findings, it has been proposed that SIV_{cpz} arose as a result of a recombination event involving SIV_{gsn} and SIV_{rcm} lineages in a West Central African monkey species upon which chimpanzees prey.²⁸ According to this model, *ptt* chimpanzees, sharing an overlapping geographical range with greater spot-nosed and red-capped monkeys in West Central Africa, would have been the first member of the great apes to be infected with the putative recombinant progenitor of SIV_{cpz}, eventually giving rise to strains of SIV_{cpzPtt}. The subsequent four cross-species transmissions to humans, thereby generating the M, N, O, and P groups of HIV-1, would be consistent with the tree locations of these primate lentiviruses (Fig. 49.4A).

GENOMIC ORGANIZATION OF HIVs

Nucleotide sequencing of several of the original HIV-1 isolates revealed an unexpected result: in contrast to the well-characterized and intensively studied prototypical retroviruses such as ASLV and MLV, whose genomes contain only three genes (*gag*, *pol*, and *env*) encoding the structural proteins and enzymes required for productive infection, the HIV-1 genome included several additional and overlapping open reading frames (ORFs) of unknown function (Fig. 49.5). Not only were HIV-1 and HIV-2 shown to contain multiple additional ORFs, but also their genomic organizations appeared to be very similar. Further analyses revealed that HIV-1 contained the distinguishing *vpu* gene^{144,726} and HIV-2 carried a signature *vpx*³⁷⁵ gene.

Like all replication-competent retroviruses, the three primary HIV-1 translation products, all encoding structural proteins or enzymes, are initially synthesized as polyprotein precursors, which are subsequently processed by viral or cellular proteases into mature, particle-associated proteins (Fig. 49.6). The 55-kD Gag precursor Pr55^{Gag} is cleaved into the matrix (MA), capsid (CA), nucleocapsid (NC), p6, and the two spacer peptides SP1 and SP2 during or after the release of progeny virions. Autocatalysis of the 160-kD Gag-Pol polyprotein, Pr160^{Gag-Pol}, gives rise to the protease (PR), the heterodimeric RT, and integrase (IN) proteins, whereas proteolytic digestion by a cellular enzyme converts the glycosylated 160-kD Env precursor, gp160, into the gp120 surface (SU) and gp41 transmembrane (TM)

"Simple" Retrovirus

"Complex" Human Retroviruses

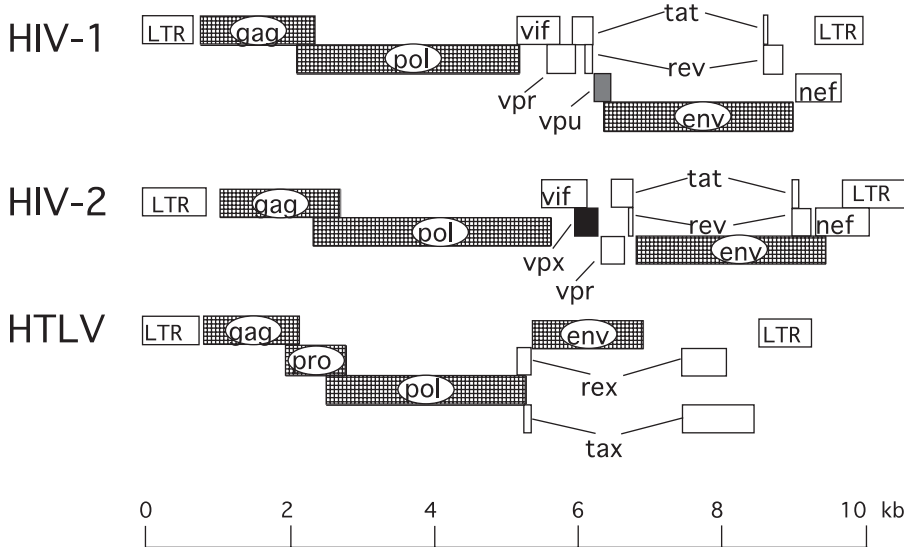

FIGURE 49.5. Genomic organization of simple and complex retroviruses. The genes of Moloney murine leukemia virus (MLV), human T-cell leukemia virus 1 (HTLV-1), human immunodeficiency virus 1 (HIV-1), and HIV-2 are depicted as they are arranged in their respective proviral DNA. The sizes of the different proviral DNA are shown in proportion to the 9.7-kb HIV provirus.

cleavage products. The remaining six HIV-1–encoded proteins (Vif, Vpr, Tat, Rev, Vpu, and Nef) are the primary translation products of spliced messenger RNAs (mRNAs).

HIV-1 and HIV-2 have incorporated multiple sequence elements into their genomic RNAs that direct the balanced and coordinated production of progeny virions. Many of these *cis*-acting RNA elements (Fig. 49.7) are present in other retroviral genomes, but a few are unique to the primate lentiviruses. The 5′ ~330 nucleotide untranslated region of HIV-1 genomic

RNA is highly structured and contains multiple elements that mediate transcriptional elongation of viral RNA transcripts, splicing, genomic RNA dimerization, packaging of full-length viral RNA, and reverse transcription. A schematic model of this 5′ leader sequence, deduced from genetic, functional, structural, and nuclease-accessibility mapping experiments, is shown in Figure 49.7, inset A.

Three regions encompassing the primer binding site (pbs) stem participate in the placement and stabilization of

FIGURE 49.6. Human immunodeficiency virus (HIV)-encoded proteins. The location of the HIV genes, the sizes of primary translation products (in some cases, polyproteins), and the processed mature viral proteins are indicated.

FIGURE 49.7. Cis-acting elements present in the human immunodeficiency virus 1 (HIV-1) genome. Elements associated with HIV-1 genomic RNA include the methyl-capped terminal G residue at the 5' terminus of viral RNA (mG), Tat-responsive stem-bulge-loop structure (TAR), binding site for the tRNA^{Lys} primer (pbs), major splice donor (MSD), RNA packaging site (ψ), frameshifting motif (FS), RNA instability or nuclear retention elements (INSSs), central polypurine tract (PPT_c), splice acceptors (arrowheads), internal splice donors (small arrows), Rev-responsive element (RRE), canonical 3' polypurine tract (PPT), and polyadenylation signal (PA). **A:** The putative secondary structure at the 5' terminus of HIV-1 messenger RNA (mRNA). The positions of the TAR stem-loop, poly(A) stem-loop, circled poly(A) addition signal (AAUAAA), pbs, dimerization initiation sequence (DIS), MSD, primer activation signal (PAS), ψ stem-loops 1 to 4 (SL1 to SL4), and translation initiation AUG codon for Gag are indicated. (**A** adapted from Carteau S, Gorelick RJ, Bushman FD. Coupled integration of human immunodeficiency virus type 1 cDNA ends by purified integrase in vitro: stimulation by the viral nucleocapsid protein. *J Virol* 1999;73:6670–6679.) **B:** The self-complementary DIS sequences, located at the crown of stem-loop 1, participate in the formation of “kissing loop” intermediates, an initial step in the RNA dimerization reaction. **C:** RNA stem-loop structure downstream of the UUUUUUA frameshifting sequence.

the transfer (t) RNA^{Lys3} primer, which is incorporated into HIV-1 particles and is required for the initiation of reverse transcription. These regions include the pbs itself, which can base-pair with the 3' terminal 18 nt of tRNA^{Lys3}; the primer activation signal (PAS), which interacts with the thymidine-pseudouridine-cytidine (T ψ C) arm of the tRNA to trigger the reverse transcription reaction; and the A-loop, which is complementary to the anticodon loop of tRNA^{Lys3} (reviewed in⁶⁰). The unwinding of both the tRNA primer and the pbs stem within the 5' untranslated region (UTR) of the HIV-1 genome, as well as the incorporation of the primer into nascent virions, is facilitated by the NC domain of the Gag polypeptide, which plays the role of a molecular chaperone in this process (reviewed in⁴⁴⁰).

The packaging of HIV-1 genomic RNA into progeny virus particles is also directed by the NC domain of the Gag polypeptide and is primarily dependent on its interaction with the four RNA stem-loops (SL1, SL2, SL3, and SL4) constituting the core encapsidation signal, ψ (Fig. 49.7A).¹⁵⁷ It is currently thought that a fully functional HIV ψ packaging signal may include the entire 5' UTR plus the first 300 nucleotides of the *gag* gene. In virions, the HIV-1 genome is present as an RNA dimer, noncovalently linked at the 5' end of each molecule. Particle-associated dimeric RNA provides an alternative template for reverse transcription, should the enzyme encounter a nick or break during the polymerization reaction. The dimerization initiation sequence (DIS), located at the crown of SL1, contains

a complementary, exposed, and palindromic sequence (Fig. 49.7, insets A and B).^{427,704} Most of the non-B/D HIV-1 subtypes, including the highly prevalent subtype C viruses, have a GTGCAC for their DIS, whereas clade B and D subtypes have a GCGCGC in their DIS. Dimerization is initiated via a *kissing loop* mechanism involving base-pairing between the palindromic sequences present on paired HIV-1 genomes.⁵⁷⁹ Other regions of SL1 participate in stabilizing the RNA dimer into a more extended duplex structure,²⁰⁷ a process also believed to be chaperoned by NC. The ψ packaging domain also contains the major splice donor (MSD) (near the crown of SL2) and the AUG Gag start codon (at the base of SL4).

It has been proposed that the HIV-1 leader can switch from the multiple hairpin structure shown in Figure 49.7A to an alternate, rod-like conformation, and that each conformer specifically promotes either packaging or translation of the viral RNA.³⁴⁰ In this model, the individual stem-loops are formed as intermediates during RNA synthesis, but the entire HIV-1 leader is eventually converted to the thermodynamically more stable rod structure containing an exposed AUG Gag start codon and an occluded DIS motif. The rod conformer, containing a masked DIS, may promote the translation of HIV-1 mRNAs into viral-encoded proteins. A subsequent switch to the alternative conformation, mediated by NC, would expose the DIS and ψ elements, favoring dimerization, packaging, and, ultimately, reverse transcription of the viral genomic RNA.^{160,575} Evidence for the existence of alternative RNA conformers in virions or infected cells and the hypothesized conformational switch is still forthcoming.

In HIV-1, the AAUAAA binding site for the cleavage and polyadenylation factor (CPSF) and the GU/U-rich binding site for the 3' terminal cleavage stimulation factor (CstF) are both situated within the repeat (R) regions at each end of the viral genomic RNA. An active 5' poly(A) site would obviously compromise the generation of long RNA transcripts by mediating premature cleavage and polyadenylation. A polyadenylation enhancer, situated upstream of the 3' poly(A) signals, stabilizes the binding of CPSF to AAUAAA and promotes poly(A) addition, whereas the 5' poly(A) stem or the closely positioned MSD has been reported to suppress polyadenylation activity.^{25,161,258}

Lentiviruses are unique among retroviruses in having a novel central polypurine tract (PPT) in addition to the canonical U3-proximal PPT, both of which are used for the synthesis of plus-strand viral DNA.¹¹⁴ The viral genomic RNA also contains a heptameric UUUUUUA “slippery” sequence within the *gag* gene where ribosomal frameshifting (FS) occurs. This sequence functions in conjunction with a downstream 8-nt spacer and hairpin (Fig. 49.7C) to mediate *minus 1* translational frameshifting.³⁵³ The viral RNA also folds into two additional complex structures (the transactivation response region [TAR] and Rev-responsive element [RRE]), which are involved in RNA synthesis and RNA nuclear-to-cytoplasmic transport, respectively. Multiple inhibitory sequences (INSSs), associated with the instability or nuclear retention of HIV transcripts, are scattered throughout genes encoding the *gag*, *pol*, and *env* genes.^{480,640} Finally, although not strictly considered a *cis*-acting element, HIV-1 genomic RNA contains a significantly higher adenosine deoxyribonucleotide (A) content (approximately 39%) than does mammalian DNA; this bias contributes to an unusual codon usage.⁵¹

The secondary structure of the entire HIV-1 genome has recently been determined using a technique called selective 2'-hydroxyl acylation analyzed by primer extension (SHAPE).⁷⁹¹ SHAPE is based on the chemical modification of unpaired nucleotides in RNA molecules and the resultant termination of reverse transcription at the altered site. Regions of RNA with significant secondary structure are not readily modified, whereas looped-out RNA segments exhibit high SHAPE reactivity. This allows the determination of the folded state of RNA using a computer algorithm.⁵⁰³ Some of the tightly base-paired RNA regions identified by SHAPE correspond to previously described TAR structures at the 5' and 3' termini of the HIV-1 genome, the SP1 encapsidation site in the 5' UTR, and the RRE (Fig. 49.7). Interestingly, structured RNA segments were also present in protein-coding regions located between individual Gag, Pol, and Env subdomains, which give rise to mature protein cleavage products. In addition, base-paired regions of HIV-1 RNA are located adjacent to sequences encoding protein domains that undergo co-translational folding or unfolding.⁷⁹¹ Ribosomal pausing induced at these structured RNA segments may retard translation to allow sufficient time for a nascent protein to attain its final conformation. Nonstructured RNA regions encoding the gp120 variable loops were enclosed by stable RNA duplexes, yet another example of co-related RNA and protein structures.

BIOLOGY OF HIV INFECTIONS

The main cellular targets for HIV-1 in infected individuals are the CD4+ T lymphocytes, CD4+ cells of the macrophage lineage, and some populations of dendritic cells (DCs). A quintessential property of HIV-1 and the other primate lentiviruses is to sequentially use CD4 and a second cellular receptor during entry into susceptible cells, a subject discussed more extensively in the section dealing with virus binding and entry. The earliest studies used mitogen-activated human PBMCs for HIV-1 isolation and propagation. Some of the original HIV-1 isolates were also able to infect continuous CD4+ T leukemia cell lines such as CEM, Jurkat, Hut-78 (including its H9 derivative), and the HTLV-1-containing MT-2 and MT-4 cell lines. Human T-cell lines were obviously more logistically tractable than PBMCs and their use greatly facilitated early molecular and genetic studies of HIV-1.

Replication and Tropism

HIV-1 isolates were initially classified on the basis of their replicative, cytopathic, and tropic properties. A majority of primary virus isolates, which replicated slowly and generated small amounts of progeny particles, were labeled “slow/low” to distinguish them from “rapid/high” HIV-1 strains, which exhibit faster infection kinetics and release high titers of virions. Some HIV-1 primary isolates, particularly those recovered from symptomatic individuals, induced syncytium formation (see Fig. 49.2B). These isolates were designated syncytium-inducing (SI) to distinguish them from non-syncytium-inducing (NSI) strains. Some SI isolates are able to infect CD4+ T-cell lines but not monocyte-derived macrophages (MDMs) and have been designated T-cell-line or TCL-tropic viruses. Cell tropism was a third property used to classify HIV-1 primary isolates. All HIV-1 strains are able to productively infect activated PBMCs;

TABLE 49.1 Tropic and Biological Properties of HIV-1 Isolates

Chemokine co-receptor used	PBMC replication	Macrophage replication	T-cell line replication	Replicative phenotype	Syncytium-inducing phenotype
X4	+	—	+	Rapid/high	++
R5	+	+	—	Slow/low	—
R5/X4	+	+	+	Rapid/high	+

some can also replicate in cultures of MDMs and have been classified as macrophage- or M-tropic. Other primary HIV-1 isolates are also able to infect both MDMs and T-cell lines; such strains have been classified as dual-tropic. Although exceptions exist, M-tropic isolates are usually NSI and “slow/low,” whereas TCL-tropic strains are frequently SI and exhibit the “rapid/high” replication phenotype. Forced passage of primary isolates in continuous CD4+ human T-cell lines has given rise to T-cell-line-adapted (TCLA) HIV-1 strains, which, in contrast to their progenitors, possess increased sensitivity to both neutralizing antibodies and soluble CD4.⁷³⁰

The discovery that α and β chemokine receptors function as co-receptors (in addition to CD4) for virus entry^{127,181,216} led to a revised classification system for HIV-1 strains (Table 49.1). Isolates are now categorized on the basis of chemokine receptor usage in fusion assays, in which CD4 and an individual co-receptor protein are expressed in reporter cells, or in entry assays, in which small-molecule co-receptor-targeted inhibitors, specific for CCR5 or CXCR4, block single-cycle or spreading viral infections in T-cell lines or human PBMCs. As indicated in Table 49.1, HIV-1 isolates using the CXCR4 receptor (now designated X4 viruses⁴⁷) are frequently TCL-tropic, SI strains that exhibit enhanced cytopathicity and more vigorous replicative properties. In contrast, HIV-1 strains exclusively using the CCR5 receptor (R5 viruses) may be M-tropic and NSI. Dual-tropic R5/X4 strains exhibiting a continuum of tropic phenotypes are frequently SI. Interestingly, most T-cell leukemia cell lines express high levels of CXCR4 but are CCR5 negative, explaining in part why primary HIV-1 isolates fail to replicate in these cells.

HIV-1 Infection of CD4+ T Lymphocytes

CCR5-using viruses are the predominant HIV-1 strains detected in recently infected individuals and remain the dominant virus throughout the asymptomatic phase of HIV-1 infection. *In vivo*, CCR5 is exclusively expressed on memory CD4+ T cells, a subset present at high levels in nonlymphoid tissues (e.g., in the gastrointestinal tract and lung).¹⁹¹ Many of these tissue-infiltrating memory CD4+ T cells are also activated. In contrast, CXCR4 is expressed on both naïve and memory CD4+ T-cell populations. In peripheral blood, where a majority of the circulating lymphocytes are naïve, 80% to 95% of the CD4+ T cells may express CXCR4, whereas only 5% to 10% produce detectable CCR5.^{280,560} Because R5 HIV-1 strains predominate in recently infected individuals, marked depletion of CCR5-expressing memory CD4+ T lymphocytes in the gastrointestinal tract has been reported, whereas more modest reductions of total CD4+ T-cell numbers in the blood occur during the acute infection.⁵¹⁶ The emergence of X4 variants

during the symptomatic phase of infection, which occurs in approximately 50% of individuals infected with clade B HIV-1, is referred to as *co-receptor switching*. It is associated with accelerated CD4+ T-cell depletion and more rapid progression to AIDS. Such infected individuals have 30- to 70-fold higher frequencies of virus-infected naïve cells than persons who harbor only R5 virus, consistent with the co-receptor usage of each HIV-1 strain.⁶⁴ The accelerated and specific decline of the naïve CD4+ T cells after the emergence of X4 strains represents an additional insult to the immune system that severely impedes CD4+ T-lymphocyte renewal and heralds the beginning of a downhill clinical course.

Studies of acute HIV and SIV/SHIV infections have shown that nonactivated CD4+ T lymphocytes in the mucosal lamina propria and draining lymph nodes are the principal virus targets during this phase of the infection.^{447,562,851} Paradoxically, the innate immune responses directed against HIV following virus acquisition induce a cascade of inflammatory cytokines that greatly increases the numbers and activation status of CD4+ T cells. In contrast to these findings, multiple studies have shown that resting PBMCs in culture are highly refractory to HIV-1 infection; no viral proteins or progeny virions are produced.^{718,843} PBMCs, activated with mitogens or following incubation with anti-CD3 and anti-CD28 monoclonal antibodies (mAbs) and propagated in the presence of interleukin-2 (IL-2), are quite susceptible to HIV-1 and produce high titers of infectious virus. The block to HIV-1 replication in noncycling cultured PBMCs is not presently understood. Indeed, cell cycle studies have shown that progression into G₁b is required to achieve productive HIV-1 infections.⁴⁰⁵ *In vivo*, activated CD4+ T lymphocytes are the main source of progeny virions. Nonetheless, an inducible reservoir of resting “latently infected” memory CD4+ T cells, containing integrated HIV-1 DNA and expressing no viral proteins, is established in exposed individuals within days of transmission and is thought to be the driving factor preventing the eradication of this viral infection.^{135,137}

During infections of human T-cell lines or CD4+ T lymphocytes, HIV-1 can spread through the cultures by two different mechanisms: (a) fluid phase diffusion of cell-free particles or (b) virological synapse (VS)-mediated cell-to-cell contact. Early studies reported that cell-to-cell transmission of HIV-1 was 10²- to 10³-fold more efficient than that of cell-free virus.¹⁸⁴ The extremely low particle-to-infectivity ratio (10⁻³ to 10⁻⁵) for HIV-1 undoubtedly contributed to the inefficient spread of cell-free virions. The formation of a VS with T cells, first reported for HTLV-1,³⁴⁴ utilizes some of the components of the immunologic synapse machinery involved in the interaction between lymphocytes and antigen-presenting cells.⁷⁰⁹ The formation of the HIV-1 VS is initiated by the binding of

gp120 in the infected cell to CD4 molecules on the surface of the target cell.³⁶⁵ This conjugate is further stabilized by interactions between leukocyte function–associated antigen (LFA) and intercellular adhesion molecules (ICAMs), which promote additional recruitment of actin, viral proteins (Gag and Env), CD4, and integrins to cell–cell contact regions. Cytoskeletal remodeling drives virus assembly in the infected cell to the plasma membrane and toward the target cell. Progeny particles released into the synaptic space enter the recipient cell by fusion with the plasma membrane or following passage through endosomal compartments.⁶⁶⁰ The co-polarization of clustered viral proteins in the donor cell with receptors in multiple adjacent recipients can also lead to the formation of polysynaptic structures.³⁶⁶ Filopodial bridges and other actin-containing tubular extensions of the plasma membrane have been reported for delivering virions to distant target cells.⁶⁹³ Inhibitors of HIV-1, including neutralizing antibodies, are able to block cell-free and cell-to-cell-mediated virus infectivity, although transfer across the VS may offer some protection from these agents.¹²¹

Although HIV-1 causes the loss of CD4+ cells in culture and depletion of this T-lymphocyte subset in virus-infected individuals, the mechanisms responsible for this cytopathic effect are still incompletely understood. HIV-1–induced killing of cultured CD4+ T cells (primary T cells and T-cell lines) occurs by necrosis or cytolysis rather than by classical apoptosis, which involves the activation of cysteinyl aspartate-requiring proteases (known as caspases).⁷² Some viral-encoded proteins including Vpr and Env are cytotoxic when expressed alone or in the context of a productive HIV infection. *In vivo*, the massive depletion of CD4+ T lymphocytes in blood and tissues during acute HIV and SIV infections is now recognized to be the result of direct virus-induced cell killing.^{506,516} Nonetheless, apoptotic CD4+ T lymphocytes are present in the peripheral blood and lymph nodes of HIV-1 seropositive individuals during the chronic phase of infection. These cells are uninfected and are thought to represent the effects of bystander cell damage due to the unrelenting and generalized immune activation, a major factor contributing to HIV-1 pathogenesis.²⁸²

HIV-1 Infection of Macrophages and Dendritic Cells

All known lentiviruses have retained the capacity to replicate in nonproliferating, terminally differentiated tissue macrophage. Unlike the oncoretroviruses, which require mitosis and dissolution of the nuclear membrane to complete a cycle of replication, HIV-1 is able to productively infect G₁ (but not G₀)-arrested macrophages. This property requires that the HIV-1 preintegration complex (PIC) be translocated through intact nuclear pores, a process in which the capsid (CA) protein modulates interactions with the nuclear transport machinery in nondividing cells⁴³² (see section on Nuclear Import). In HIV-1–positive individuals, infected macrophages contribute to viral persistence and dissemination to the central nervous system (CNS). HIV-1 is thought to enter the CNS very soon following transmission as virus-free particles or by the trafficking of infected lymphocytes (and possibly infected monocytes). HIV-1 does not productively infect neurons but instead targets perivascular macrophages in the choroid plexus and parenchymal microglial cells. Multinucleated giant cells, suggestive of virus-induced fusion of microglia and/or macrophages, are a histopathologic characteristic of HIV-1–associated neuropathy.

Neurologic dysfunction affecting the CNS and the peripheral nervous system is observed in 40% to 70% of virus-positive individuals. HIV-1 replication in monocyte/macrophage lineage microglia within the CNS may persist in patients receiving HAART because of inefficient transfer of drugs across the blood–brain barrier. This viral reservoir, as well as HIV-1 present in latently infected memory CD4+ T cells, could contribute to the rebound of plasma viremia invariably observed after cessation of antiretroviral drug administration.

Virtually all information pertaining to HIV-1 replication in macrophages derives from studies of an *in vitro* surrogate: monocyte-derived macrophage (MDM). The vigorous replication by M-tropic viral strains in MDM requires that blood-derived monocytes undergo differentiation *in vitro*.⁶⁸² MDMs and tissue macrophages express lower surface levels of CD4, CCR5, and CXCR4 than CD4+ T lymphocytes.^{441,788} Nonetheless, only M-tropic R5 HIV-1 strains are able to initiate infections of MDM and only a subset of M-tropic viruses are also neurotropic.³²⁶ Most primary HIV-1 isolates from blood are weakly M-tropic; strong macrophage tropism is mainly seen with variants from tissues such as the CNS, where macrophage dependence is paramount.⁵⁹⁸ Like productive infections of T lymphocytes, HIV-1 replication in MDMs requires integration of the reverse transcript.²⁰⁶ However, in contrast to numerous reports demonstrating that assembly and release of progeny virions occur at the plasma membrane of productively infected T cells, electron microscopy of HIV-1–infected MDM revealed accumulations of particles within intracellular vacuoles of endosomal origin.^{576,589} This interpretation has been questioned by reports showing that particles within putative internal vesicles were in a compartment, distinct from multivesicular bodies, which communicates with the exterior through tubular channels continuous with the highly invaginated macrophage plasma membrane.^{45,180,798} In fact, a recent study employing electron tomography and electron microscopy with stereology has reported that MDMs release progeny virions into a pre-existing membranous compartment, contiguous with the plasma membrane, which expands in size during HIV-1 infection.⁷⁹⁷ Virus particles that assemble in this internal compartment in MDMs are rapidly translocated to the VS following contact with susceptible T cells.²⁷⁷

DCs are antigen-presenting cells that capture, transport, and present antigens to CD4+ and CD8+ T lymphocytes. Two main subtypes of DCs have been identified: myeloid DCs (MDCs) and plasmacytoid DCs (PDCs). MDCs reside in multiple tissues including the skin (where they are called Langerhans cells) and the intestinal and genital tract mucosa. The less abundant PDCs are found in the blood, T-cell zones of lymph nodes, and thymus and can be recruited to sites of inflammation. After activation, MDCs secrete IL-12, whereas PDCs produce type I interferons and inflammatory cytokines. MDCs present near mucosal surfaces may represent the first line of defense against sexually transmitted HIV-1, transporting virus particles from this portal of entry to draining lymph nodes where they are degraded into antigenic peptides for presentation to CD4+ T lymphocytes. Paradoxically, this critical initial response exacerbates the HIV-1 acute infection by delivering virus to the very T-cell subset that is susceptible to and can massively amplify progeny virus production. Because of the low abundance of DCs in tissues and the small number of these cells recoverable from clinical specimens, most studies evaluating the interaction

of DCs with HIV-1 have used monocytes differentiated in the presence of granulocyte-macrophage colony-stimulating factor (GM-CSF) and IL-4. These derivatives are known as monocyte-derived DCs (MDDCs).

Productive HIV-1 infections of MDDCs are very inefficient compared to infections of activated CD4⁺ T cells, although vigorous virus replication is observed when DCs are first pulsed with virus and then co-cultivated with CD4⁺ T lymphocytes, a process called *trans-infection*.²⁵⁹ Immature DCs (IDCs) express relatively low levels of CD4, CCR5, and CXCR4 and larger amounts of C-type lectin receptors (CLRs) such as dendritic Cell-Specific Intercellular adhesion molecule-3-Grabbing Non-integrin (DC-SIGN) and dendritic cell immunoreceptor (DCIR), which capture HIV by binding to gp120-associated high-mannose glycans. Functionally, maturation of DCs leads to (a) increased capacity to degrade and present antigen to T cells by forming immunologic synapses, (b) augmented secretion of T-cell co-stimulatory molecules, and (c) potent suppression of endolysosomal degradation. Cell surface CLR expression, including that of DC-SIGN, is markedly reduced in mature DCs; capture of HIV-1 is now considered to be CLR, gp120, and CD4 independent in mature DCs.

Early studies reported that HIV-1 was internalized in trypsin-resistant, low-pH compartments for several days in MDDCs or cells expressing DC-SIGN.⁴¹⁵ Co-cultivation with activated CD4⁺ T cells resulted in rapid *trans-infection*.²⁵⁹ EM analyses of infected MDDCs indicated that intact HIV particles were present within cytoplasmic vesicles. Subsequent imaging studies, using green fluorescent protein (GFP)-labeled HIV, revealed that DCs transferred virus to T cells via a VS, utilizing adhesion molecules similar to those used in the formation of the immunologic synapse.⁴¹⁵ Virions in the infected DC were co-polarized with CD4 and chemokine co-receptors in the T lymphocyte at the cell interfaces. More recent experiments have shown that in DCs, HIV-1 resides in a unique surface-accessible intracellular compartment, distinct from endocytic vesicles, and can rapidly traffic to the VS following contact with T cells.⁸³⁷ This unusual DC compartment communicates with the extracellular environment and, similar to structures present in HIV-1-infected macrophages, is composed of highly folded invaginations of the plasma membrane.^{45,798} DC-SIGN/gp120-mediated HIV-1 entry into IDCs by endocytosis very likely results in extensive degradation of viral proteins by an active endocytic system primed for antigen presentation. Consequently, IDCs would only transmit residual nondegraded HIV remaining on their surfaces to T lymphocytes. In contrast, mature DCs, unable to endocytose HIV in a normal fashion, sequester virions in specialized intracellular compartments and, during antigen presentation, rapidly transfer infectious particles to CD4⁺ T cells. Recent studies indicate that HIV-1 infection of DCs, and to a lesser extent mature DCs, is restricted by the interferon-induced host factor SAM domain and HD domain-containing protein 1 (SAMHD1).^{46,328,418} The ability of SAMHD1 to interfere with lentiviral infection is counteracted by Vpx (see section on Vpx).

HIV-1 ANIMAL MODELS

Chimpanzees

In the search for an HIV-1 animal model during the early phase of the AIDS epidemic, cell suspensions from virus-infected individuals were inoculated into a variety of mammalian spe-

cies including nonhuman primates, but only chimpanzees consistently became infected. It was subsequently shown that asymptomatic HIV-1 infections could readily be established in chimpanzees, but viremia was not maintained and no long-standing impairment to the immune system occurred.²⁴ This could reflect genetic changes, which occurred in the SIV_{cpz} progenitor of HIV-1 following its transmission from chimpanzees and adaptation to humans.⁶⁶³ The failure of chimpanzees to develop disease in a timely fashion following inoculation with tissue culture-adapted or patient-derived HIV-1 isolates, coupled with their endangered species status, has curtailed their use as an animal model of HIV-1-induced immunodeficiency.

Transgenic Mice

When it became apparent that HIV-1 infections could only be established in chimpanzees and humans, potentially more tractable and novel rodent systems were developed to model specific steps of *in vivo* HIV-1 infections. In one approach, transgenic mice containing the entire HIV-1 genome or individual viral genes under the control of the HIV-1 long terminal repeat (LTR) were constructed. Because mice carrying such transgenes contain HIV-1 DNA in every cell, they model the postintegration phase of the virus life cycle and provide a means for assessing possible deleterious effects of viral proteins *in vivo*. In general, these first-generation transgenic animals expressed very low levels of HIV-1 proteins and occasionally developed disease.

To overcome the intrinsically low levels of HIV-1 LTR-directed expression in rodents, transgenic mice were subsequently generated carrying viral genes under the control of cellular/tissue-specific promoters. In particular, mice carrying a complete copy of the HIV-1 genome or just the *nef* gene, directed by a chimeric (human-mouse) CD4 promoter/enhancer element, spontaneously developed an AIDS-like disease characterized by marked depletion of CD4⁺ T lymphocytes, thymic atrophy, T-cell activation, and immunodeficiency.^{292,618} Thus, targeting HIV-1 Nef synthesis to mouse CD4⁺ cells, in the absence of a spreading viral infection or the expression of other HIV-1 gene products, was sufficient to elicit a disease with some of the features of human AIDS.

Xenotransplantation Mouse Models

In addition to their use for investigations of human hematopoiesis, innate and adaptive immunity, cancer biology, and regenerative medicine, mice engrafted with human cells have been utilized as a small-animal model for studies of HIV-1 pathogenesis and vaccine development. In very early studies, severe combined immunodeficiency (SCID) mice, engrafted with human PBMC or fragments of human fetal thymus and fetal liver engrafted under the renal capsule, were shown to support HIV-1 replication and moderate to profound depletions of CD4⁺ T lymphocytes but generated no immune responses to the virus.^{543,554} Relatively low levels of human cell engraftment were achieved in these first-generation humanized mice.

Although the subsequent development of nonobese diabetic (NOD) SCID animals resulted in improved human PBMC engraftment, the relatively short life span of the mice and residual murine natural killer (NK) cell activity limited their usefulness. Targeted mutations of the mouse interleukin-2 receptor- γ chain ($\gamma_c^{-/-}$) and reconstitutions with PBMC, hematopoietic stem cells (HSCs), or human cord blood greatly increased engraftment of human tissue.³⁴⁸ Inoculation of these mice with HIV-1 by parenteral and mucosal routes

resulted in sustained disseminated infections.^{27,49} The recently described surgical implantation of fetal thymic and liver tissues in humanized mice previously engrafted with HSCs resulted in animals able to support high levels of HIV viremia, experience CD4+ T-cell depletion, sustain generalized immune activation, and generate virus-specific antibody and CD4+/CD8+ T-cell responses.⁸¹ Although great progress has been made in the development of xenotransplant mouse models over the past 20 years, they are technically demanding to make and not currently amenable for widespread use.

SIV/HIV Chimeric Viruses

When it became apparent that humans and chimpanzees were the only mammalian species that could be infected by HIV-1, attention turned to the SIV/Asian macaque model with the idea of constructing a virus containing both SIV and HIV gene segments. The earliest versions of these SIV/HIV chimeric viruses (SHIVs) consisted of the genetic backbone of SIV_{mac239}, into which the HIV-1 *tat*, *rev*, *vpr*, and *env* and, in some instances, portions of *vpr* and *nef* genes were inserted (e-Fig. 49.1). SHIVs were constructed because, unlike SIVs, they could be used as challenge viruses in vaccine experiments to monitor the effectiveness of immunogens eliciting antiviral neutralizing antibodies directed against the HIV-1 Env glycoprotein. The first pathogenic SHIVs developed all carried X4-tropic *env* genes and caused a rapid, systemic, and complete loss of CD4+ T lymphocytes within a few weeks of inoculation, high and sustained levels of viremia (>10⁷ RNA copies/mL of plasma), and death from immunodeficiency within 3 to 6 months of inoculation.^{345,361,622} This aggressive disease phenotype appeared to be ideally suited for vaccine studies and, for a few years (2000 to 2004), SHIVs rather than SIVs became the challenge virus of choice for such experiments. However, concern was raised when the results from many studies showed that although most vaccine regimens suppressed SHIV replication and disease induction, they failed to protect monkeys from acquisition of either SHIV or SIV infection. In addition, differences were demonstrated between the chemokine receptor utilization of SIV (CCR5) and most transmitted HIV-1 (CCR5) versus the early SHIVs (CXCR4) and the CD4+ T-cell subsets targeted by these viruses *in vivo* (memory [SIV and HIV-1] versus naïve [SHIV]).⁵⁶³ The development and use of R5-tropic SHIVs as challenge viruses in macaques were shown to be better surrogates for HIV-1 infections of humans.²⁹⁸

Derivatized HIVs (also known as minimal SHIVs), containing more than 90% of the HIV-1 genome and the SIV *vif* gene (to counteract macaque APOBEC3 proteins) plus a seven–amino acid segment of the SIV Gag analog of the HIV-1 cyclophilin A (CypA)-binding loop (to escape macaque TRIM5 α [for tripartite motif-containing α] restriction), have recently been reported to establish transient infections in pig-tailed macaques.³⁴⁶ When it was subsequently appreciated that pig-tailed macaques lacked TRIM5 α restriction activity against HIV-1, derivatized HIVs, containing only the SIV *vif* gene, were made and shown to transiently infect this monkey species.³⁰³

MOLECULAR BIOLOGY OF HIV-1 REPLICATION

Overview

The HIV-1 replication cycle (Fig. 49.8) begins with the binding of virus particles to CD4 molecules on the surface of susceptible

cells. In the context of tissue culture systems, susceptible cells include *activated* CD4+ T lymphocytes present in PBMC collected from uninfected individuals, T-cell leukemia cell lines, and MDMs. *In vivo*, activation of CD4+ T cells is not required for HIV-1 replication. Although binding of virions to CD4 is essential for HIV infectivity, their subsequent interaction with a co-receptor, now known to be members of the seven-membrane-spanning CC or CXC families of chemokine receptors, is required for membrane fusion and entry (reviewed in¹³). Multiple chemokine receptors exhibit activity in fusion/entry assays with HIV-1 gp120 (see later section on Env); however, the two most physiologically important co-receptors are CXCR4 and CCR5. Unlike some other enveloped viruses that enter cells by receptor-mediated endocytosis, HIV-1 and many other retroviruses fuse directly with the plasma membrane. Once inside the cell, HIV-1 encounters a cortical actin barrier, which can be remodeled by the virally encoded Nef protein. Partially uncoated virions migrate from cortical actin to the microtubule network where reverse transcription is initiated and movement to the nucleus begins (Fig. 49.8, steps 2 to 4) (reviewed in¹⁸). As with other retroelements, the partially double-stranded DNA reverse transcription product is transported through the cytoplasm and to the nucleus as a component of a PIC, which contains a subset of the Gag and Pol proteins. As noted earlier, the lentiviruses are unique among retroviruses in generating PICs that are actively transported by the nuclear import machinery into the interphase nucleus of nondividing cells arrested in the G₁ phase of the cell cycle (Fig. 49.8, step 5). After the import of the PIC into the nucleus, full-length linear copies of the reverse transcript are integrated into the chromosomal DNA of the infected cell (Fig. 49.8, step 6), a step required for efficient viral RNA synthesis and infectious particle production.

In activated T lymphocytes, integrated copies of HIV DNA serve as templates for RNA polymerase II (Pol II)-directed viral RNA synthesis (Fig. 49.8, step 7). The coordinated interaction of the HIV-encoded Tat protein and the cellular NF- κ B and Sp1 transcriptional transactivating proteins with the RNA Pol II transcriptional apparatus ensures the production of high levels of viral RNA. Unspliced or partially spliced HIV transcripts are exported from the nucleus to the cytoplasm by a unique transport mechanism mediated by the virus-encoded Rev protein, which shuttles between these compartments (Fig. 49.8, step 8). The subsequent translation of the gp160 Env precursor occurs in the endoplasmic reticulum, whereas the Gag and Gag-Pol polyproteins are synthesized on free cytoplasmic ribosomes, and each is independently transported to the plasma membrane (Fig. 49.8, steps 9 and 10). The Gag and Gag-Pol polyproteins, in association with dimers of genomic RNA, condense at the plasma membrane to form an electron-dense “bud” (see Fig. 49.2) that gives rise to a spherical immature particle containing the mature TM and SU Env glycoproteins. Proteolytic processing of the Gag and Pol proteins by HIV PR during or immediately after particle release generates the cone-shaped core characteristic of mature HIV virions (Fig. 49.8, steps 11 and 12).

Thus, HIV-1 uses the same replicative strategy as the so-called simple retroviruses, which encode only the Gag, Pol, and Env proteins. However, during its evolution, HIV-1 has acquired six additional genes to carry out functions that are either (a) performed by cellular proteins already present in the cells infected by the simple retroviruses or (b) uniquely required for virus replication, transmission, and survival in hematopoietic

FIGURE 49.8. The human immunodeficiency virus type 1 (HIV-1) replication cycle. Productive HIV-1 infections begin with the adsorption of cell-free virions to cells and their interactions with both the CD4 and chemokine co-receptors (**step 1**). In the case of HIV, virus entry (**step 2**) is a pH-independent process that occurs after the fusion of viral and cellular membranes and results in the partial uncoating (**step 3**) of incoming virions. Reverse transcription occurs within subviral particles in the cytoplasm of infected cells (**step 4**), and the double-stranded DNA product within this preintegration complex (PIC) is transported into the nucleus (**step 5**), where integration into chromosomal DNA (**step 6**) is mediated by the virus-encoded integrase (IN) (open circles). The integrated viral DNA serves as a template for DNA-dependent RNA polymerase (Pol II) and leads to the production of messenger RNAs (mRNAs) (**step 7**), some of which are spliced and exported into the cytoplasm (**step 8**), where they are translated into viral proteins. Envelope (**step 9**) and Gag plus Gag-Pol (**step 10**) polyproteins are transported via independent pathways to the plasma membrane, where progeny virus particles begin “budding” from cells and are released as immature particles (**step 11**). Subsequent proteolysis by the virion-encoded protease (PR) generates mature particles (**step 12**) containing a characteristic condensed core. Non-virion-associated gp120 Env glycoprotein is also released from cells (**step 13**).

cells targeted by the primate lentiviruses. Some of the HIV-1 accessory proteins (Vif, Vpr, Vpu, and Nef) are not required for replication in certain human T-cell lines, although virus infectivity may be affected up to several thousandfold, depending on the accessory gene and the type of infected cell. In view of their conservation, however, these additional genes must be required for successful HIV-1 infectivity *in vivo*.

HIV-1 encodes only 15 proteins and like all other viruses must utilize a large number of cellular proteins for successful replication. Over the years, several techniques, such as immunoprecipitation/mass spectrometry and yeast two-hybrid screening, have been used to identify such host cell factors. The recent development of genome-wide small-interfering RNA (siRNA) or short hairpin (shRNA) screening has provided genetic approaches to identify potential human proteins required for HIV-1 replication, based on loss of function readouts.^{82,404,836,857} In these experiments, siRNAs are transfected into target cells, whereas shRNAs are delivered using lentiviral vectors and subsequently processed into siRNAs intracellularly.

Of the 842 genes identified as being required for HIV-1 replication in three siRNA screens, 34 were also reported in at

least two screens and three were detected in all three screens. The overlap between the three siRNAs and the single shRNA screen ranged from zero to three genes in pairwise comparisons. Eleven of the 34 genes found in two siRNA screens had also been previously reported to encode HIV-1-interacting proteins and 29 of the 34 genes are expressed in cells susceptible to HIV-1 (CD4 and chemokine coreceptor positive). The overlap between individual screens is unexpectedly small yet is statistically significant.⁹² This result is not surprising given that different challenge viruses, cell lines, siRNA libraries, periods of gene silencing prior to infection, and readouts of infection were used in the four studies. Nonetheless, all three siRNA screens identified factors associated with transport through the nuclear pores, trafficking between cellular compartments, DNA repair, RNA binding, and interaction with ubiquitin/proteasomal degradation machinery.⁹² Two of the siRNA screens identified previously reported cellular proteins known to be critical for HIV-1 infectivity including CD4, CXCR4, RelA, elongin B, and cyclin T1. Cyclophilin A, Sp1, and lens epithelium-derived growth factor (LEDGF) are among the known HIV-1 co-factors that were *not* identified in any of the screens.

FIGURE 49.9. Linear representation of the human immunodeficiency virus 1 (HIV-1) Env glycoprotein. The vertical arrow indicates the site of gp160 cleavage to gp120 and gp41; SP denotes the signal peptide. In gp120, variable domains (V1 to V5) and conserved sequences (C1 to C5) are indicated. In the gp41 ectodomain, several domains are indicated: the N-terminal fusion peptide (FP) and the two heptad repeats (HR1 and HR2). The transmembrane domain (TMD) is represented by a yellow box. In the ~150 amino acid gp41 cytoplasmic tail (CT), the Tyr-Ser-Pro-Leu (YSPL) and Leu-Leu (LL) motifs implicated in Env trafficking and internalization are indicated. The putative helical motifs—or lentiviral lytic peptides (LLP-1, LLP-2, and LLP-3)—are shown. (Adapted from Checkley MA, Luttge BG, Freed EO. HIV-1 envelope glycoprotein biosynthesis, trafficking, and incorporation. *J Mol Biol* 2011;410:582–608, copyright 2011, with permission from Elsevier.)

Virus Binding and Entry: The Env Glycoproteins

The HIV Env glycoproteins are synthesized from the singly spliced 4.3-kb Vpu/Env bicistronic mRNA (see Fig. 49.6); translation occurs on ribosomes associated with the rough endoplasmic reticulum (RER). The Env glycopolyprotein precursor, gp160, is an integral membrane protein that is anchored to cell membranes by a hydrophobic stop-transfer signal in the gp41 TM domain (Fig. 49.9) (reviewed in¹¹⁷). gp160 is co-translationally glycosylated and undergoes oligomerization in the endoplasmic reticulum (ER). The predominant, biologically active oligomeric form is a trimer. gp160 is transported to the Golgi, where, like other retroviral Env precursor glycoproteins, it is proteolytically cleaved by a cellular enzyme to the mature SU and TM glycoproteins, gp120 and gp41, respectively (Fig. 49.9). The cellular enzyme primarily responsible for cleavage of retroviral Env precursors following a highly conserved Lys/Arg-X-Lys/Arg-Arg motif is furin or a furin-like protease.²⁸⁸ Cleavage of gp160 is strictly required for Env-induced fusion activity and virus infectivity.^{237,510} Subsequent to gp160 cleavage, gp120 and gp41 form a noncovalent association that is critical for transport of the Env complex from the Golgi to the cell surface. The gp120–gp41 interaction is fairly weak, and a substantial amount of gp120 is shed from the surface of Env-expressing cells.

The HIV Env glycoprotein complex, in particular the gp120 component, is very heavily glycosylated; approximately half the molecular mass of gp160 is composed of oligosaccharide side chains. During transport of Env from its site of synthesis in the ER to the plasma membrane, many of the side chains are modified by the addition of complex sugars. The numerous oligosaccharide side chains form a sugar “cloud,” obscuring much of gp120 from host immune recognition. As

shown in Figure 49.10, gp120 contains interspersed conserved (C1 to C5) and variable (V1 to V5) domains. The Cys residues present in the gp120 proteins of different isolates are highly conserved and form disulfide bonds that link the first four variable regions in large loops.⁴³⁷

After its arrival at the cell surface, the gp120–gp41 complex is rapidly internalized. Several studies have demonstrated that a Tyr-X-X-Leu sequence in the gp41 cytoplasmic tail (approximately five residues from the membrane-spanning domain) (see Fig. 49.9) is at least partially responsible for this rapid internalization.^{417,645} Analogous motifs are also present in the TM Env proteins of HIV-2, SIV, and several other retroviruses. Tyr-based motifs are known to mediate endocytosis of cellular plasma membrane proteins by binding the μ 2 chain of clathrin-associated adaptor protein-2 (AP-2) complexes, and such interactions have been observed with the HIV-1 and SIV gp41 cytoplasmic domains.^{69,568} A dileucine motif at the C-terminus of the gp41 cytoplasmic tail also participates in Env internalization and trafficking via interactions with the AP-1 complex^{52,94,820} (Fig. 49.10). Rapid Env internalization could help HIV-1 evade the host immune response and limit Env-induced cytopathicity. The cytoplasmic tail of HIV-1 and SIV gp41 has also been reported to activate NF- κ B, potentially providing a stimulus for T-cell activation, thereby enhancing viral infection.⁶¹²

CD4 Binding

The first step in HIV/SIV infection involves an interaction between gp120 and CD4, the major cell surface receptor for primate lentiviruses (for review, see⁷⁷). CD4 is a 55-kD member of the immunoglobulin (Ig) superfamily; it is composed of a highly charged cytoplasmic domain, a single hydrophobic

FIGURE 49.10. Ribbon diagram of the gp120 core. In this orientation, the viral membrane would be at the top, the target cell membrane at the bottom. The inner and outer domains are connected by a four-stranded β -bridging sheet. The remnants of variable loops V1/V2, V3, V4, and V5 are shown. (Reprinted from Kwong PD, Wyatt R, Robinson J, et al. Structure of an HIV gp120 envelope glycoprotein in complex with the CD4 receptor and a neutralizing human antibody. *Nature* 1998;393:648–659. Copyright © 1998, *Nature*.)

membrane-spanning domain, and four distinct extracellular domains, D1 to D4.⁴⁷⁵ CD4 normally functions to stabilize the interaction between the T-cell receptor on the surface of T lymphocytes and class II major histocompatibility complex (MHC-II) molecules on antigen-presenting cells. The high-affinity CD4 binding site for gp120 has been localized to a small segment of the N-terminal extracellular domain, analogous to the second complementarity-determining region (CDR-2) loop of an Ig light chain variable domain. CD4 binding determinants in Env map to the C3 and C4 domains of gp120, although a more discontinuous, conformation-dependent domain is involved in high-affinity gp120–CD4 binding. CD4 binding serves not only to promote virion attachment to the target cell but also to induce conformational changes in gp120 and gp41 that activate Env fusogenicity.^{661,751} In most HIV-1 isolates, CD4 binding induces conformational changes in gp120 that promote gp120 binding to co-receptors.

The crystallization of a gp120 “core” domain (an unglycosylated gp120 derivative lacking the V1/V2 and V3 loops and the N- and C-termini) complexed with fragments of CD4 and a neutralizing antibody contributed greatly to our understanding of the gp120–CD4 interaction.^{416,819} The core structure reveals two major domains (referred to as the “inner” and “outer” domains) connected by a so-called bridging sheet (see Fig. 49.10). The latter is composed of a four-stranded, antiparallel β -sheet derived from sequences in the V1/V2 stem and portions of C4. Comparison of the CD4-bound HIV-1 gp120 structure with that of the non-CD4-bound (unliganded) gp120 from SIV_{mac} reveals that gp120, the inner domain in particular, undergoes a remarkably extensive conformational change upon CD4 binding.¹¹⁸ This shift in conformation leads to the formation of the bridging sheet, which is absent in the unliganded structure.

Co-receptor Interactions

Soon after the identification of CD4 as the major HIV/SIV receptor, it was recognized that this protein is not sufficient for HIV-induced membrane fusion and virus entry. In the mid-1990s, a number of studies demonstrated that members of the G protein-coupled receptor superfamily of seven-transmembrane domain proteins provided the long-sought co-receptor function.^{14,127,181} As mentioned earlier, the two major co-receptors for HIV/SIV infection are CXCR4 and CCR5. In recognition of the importance of CXCR4 and CCR5 in determining HIV-1 tropism, a nomenclature scheme was devised based on co-receptor usage: viruses (generally M-tropic) that use CCR5 are denoted R5 isolates, strains (generally TCL-tropic) that preferentially use CXCR4 are referred to as X4 viruses, and dual-tropic strains that use both CCR5 and CXCR4 are denoted R5/X4 isolates⁴⁷ (Table 49.1).

Since the discovery of HIV/SIV co-receptors, numerous additional studies refined our understanding of the activity and function of these proteins. Some of the more important findings are described here; for further information, the reader is referred to more-detailed reviews.⁴⁸

- It is clear that, depending on the virus isolate, multiple sequences in the N-terminal domain and extracellular loops of CCR5 and CXCR4 can influence co-receptor function, and that the gp120–co-receptor interaction is complex.
- Certain laboratory isolates of HIV-1, HIV-2, and SIV use co-receptors in a CD4-independent manner, that is, as primary receptors.^{205,499,613} In fact, the identification of CD4-independent HIV and SIV isolates suggests that the use of chemokine receptors in lentiviral infection may have predated the involvement of CD4.

- Direct interactions between co-receptor and gp120 have been detected. These interactions are greatly stimulated by, or are dependent on, the presence of CD4.^{425,758,816}
- In addition to CXCR4 and CCR5, a number of other chemokine receptors and related proteins can serve as co-receptors for HIV/SIV fusion and infection in cultured cells. These include CCR2b, CCR3, CCR8, APJ, Bonzo (STRL33), BOB (GPR15), and US28 (for review, see⁴⁸). What role, if any, these alternative co-receptors play in HIV/SIV infection *in vivo* is unclear.

Several domains within gp120 directly or indirectly function in Env–co-receptor interactions. Consistent with its influence on HIV-1 tropism, the V3 loop plays a major role. In addition to the involvement of variable regions in co-receptor interaction, highly conserved portions of gp120 also interact with co-receptors. Following the initial report of the gp120 core crystal structure in 1998, a number of additional HIV-1 and SIV gp120 structures have been published. Together, these structures have provided a number of key insights into the gp120 structure/function relationship. As mentioned earlier, gp120 undergoes extensive conformational changes upon binding to CD4. Particularly significant is that the co-receptor binding site is essentially created following CD4 binding.¹¹⁸ As a result, the co-receptor binding site, which would be highly susceptible to neutralizing antibodies, exists only transiently after gp120 has contacted CD4 on the target cell membrane. These structural findings are consistent with earlier reports demonstrating that binding of antibodies to the co-receptor-interacting surface of gp120 is enhanced by CD4.^{662,751} Interestingly, the co-receptor–binding surface is constitutively exposed in variants selected to replicate in a CD4-independent fashion.^{322,402} Because their co-receptor–binding surface is

constitutively exposed, CD4-independent isolates tend to be hypersensitive to neutralization.

Certain individuals, despite persistent high-risk behavior, remain HIV-1 uninfected. The discovery of CCR5 and CXCR4 as HIV-1 co-receptors raised the possibility that these individuals inherited mutant co-receptor alleles. Indeed, a mutant CCR5 allele, referred to as CCR5/Δ32, contains a 32-bp deletion and encodes a truncated protein that is not efficiently expressed at the cell surface and cannot function as an HIV-1 co-receptor.^{176,335,457,654} Homozygotes for CCR5/Δ32 are only rarely infected with HIV-1, highlighting the protective benefits of inheriting this allele. Other inherited polymorphisms in co-receptor coding regions or regulatory sequences have been reported to influence HIV-1 transmission or HIV-1-induced disease progression, though the effects are not as clear as with the CCR5/Δ32 allele.

Membrane Fusion

The primary function of viral Env glycoproteins is to promote a membrane fusion reaction between viral and target cell membranes. This membrane fusion event enables the viral core to gain entry into the host cell cytoplasm. The observation that CD4 induces conformational changes in gp120 that enhance interaction with co-receptors suggests that events leading up to membrane fusion occur sequentially (Fig. 49.11). gp120 first interacts with CD4; a ternary CD4–co-receptor–gp120 complex then forms; and finally, conformational changes take place in gp41 that trigger membrane fusion. Although fusion between the viral and cellular membrane is widely believed to occur directly at the plasma membrane after CD4 and co-receptor engagement, it has been reported that fusion can also occur in a low-pH endosomal compartment.⁵²⁷

FIGURE 49.11. Schematic representation of the steps leading to membrane fusion.

In the resting configuration, the Env glycoprotein complex is in its native state (1). CD4 binding (2) induces conformational changes in Env that facilitate coreceptor binding (3). After the formation of a ternary gp120–CD4–coreceptor complex, gp41 adopts a hypothetical conformation that allows the fusion peptide to insert into the target lipid bilayer (4). The formation of the gp41 six-helix bundle, which involves antiparallel interactions between the gp41 heptad repeats (HR1 and HR2) (5), brings the viral and cellular membranes together and membrane fusion takes place (6).

Mutational analyses demonstrated that a hydrophobic region at the N-terminus of gp41, the so-called fusion peptide, plays a central role in membrane fusion mediated by HIV-1,²³⁵ HIV-2,²³⁴ and SIV⁷⁴ (see Fig. 49.9). C-terminal to the gp41 fusion peptide are two amphipathic heptad repeat (HR) domains (see Fig. 49.9) that are also required for membrane fusion. Mutations in the N-terminal HR (HR1) impair infectivity and membrane fusion activity,¹⁹⁵ and peptides derived from HR1 and HR2 exhibit potent antiviral activity in culture.⁸⁰² Structures for the ectodomain of HIV-1 and SIV gp41, including the HRs, were determined by x-ray crystallography and nuclear magnetic resonance (NMR) spectroscopy.^{95,113,743,795} These studies obtained fundamentally similar trimeric structures in which HR1 and HR2 pack in an antiparallel fashion to generate a six-helix bundle (Figs. 49.11 and 49.12). The HR1s form a coiled-coil in the center of the bundle, with the HR2s packing into hydrophobic grooves on the outside. The gp41 ectodomain structure resembles that of the fusion-competent (low-pH-induced) form of influenza HA₂, making it likely that HIV/SIV Env glycoproteins trigger membrane fusion by the same “spring-loaded” mechanism proposed for influenza virus.⁹¹ Peptides corresponding to the HRs inhibit fusion (and virus infectivity) by interacting with their

FIGURE 49.12. Trimeric structure of simian immunodeficiency virus (SIV) gp41 ectodomain residues 27 to 149. The N-terminal heptad repeats (HR1s) are located on the inside of the six-helix bundle; the C-terminal heptad repeats (HR2s) pack into hydrophobic grooves on the outside. The three subunits are shown in green, blue, and red. (Reprinted from Caffrey M, Cai M, Kaufman J, et al. Three-dimensional solution structure of the 44 kDa ectodomain of SIV gp41. *EMBO J* 1998;17:4572–4584, with permission from Oxford University Press.)

complementary binding partner on gp41, thus preventing gp41 itself from forming the six-helix bundle. Binding studies using native HIV-1 Env indicate that gp41 interacts with HR2 peptide only after CD4 binding, suggesting that HR1 and HR2 undergo conformation changes after CD4 binding and that these rearrangements are required for membrane fusion.²⁴⁴ The cytoplasmic domain of gp41 also plays a role in modulating the fusion activity of Env, in part by regulating the levels of cell surface expression of the gp120–gp41 complex and by influencing the conformational of gp120 and the ectodomain of gp41 (for review see¹¹⁷).

Whereas gp41 interacts directly with the lipid bilayer to catalyze the membrane fusion reaction, a variety of domains within gp120 are involved in activating Env fusogenicity. The V3 loop of HIV-1 gp120, which elicits isolate-specific neutralizing antibodies, is an essential player in membrane fusion. Mutations throughout the V3 loop of HIV-1²³⁶ and the analogous region of HIV-2²³⁴ block syncytium formation and virus infectivity. The importance of V3 in membrane fusion appears to be in part a consequence of its role in gp120–co-receptor interactions. The structure of the V3 loop in the context of the CD4-bound gp120 core reveals that V3 protrudes out from the core, toward the target cell membrane and the co-receptor.³³¹

It has become apparent that the lipid composition of the target cell plasma membrane plays an important role in membrane fusion. Of particular interest is the concept that membrane fusion may take place in plasma membrane microdomains known as lipid rafts. These microdomains, which are enriched in glycosphingolipids and cholesterol, appear to be involved in the entry of a number of enveloped viruses, including HIV-1 (for review see⁷⁸⁴). Depletion of cholesterol from either the virus particle or the target cell membrane disrupts fusion,⁵⁷³ as does depletion of specific glycosphingolipids.^{88,336} The cholesterol-binding compound amphotericin B methyl ester (AME) is also a very potent inhibitor of HIV-1 infectivity.⁷⁸² Interestingly, HIV-1 evades AME by acquiring mutations in the cytoplasmic tail of gp41 that cause the tail to be cleaved by PR, thereby allowing infection to proceed even in the presence of the inhibitor.⁷⁸³ In addition to promoting cell-free HIV-1 infection, lipid rafts may play an important role in HIV-1 transmission between T cells³⁶⁶ and in virus uptake into DCs.⁹⁷

Progress in understanding the molecular mechanism of membrane fusion has led to the development of inhibitors that block virus fusion and entry (for review see⁷⁵²). One of these fusion inhibitors, T-20 (enfuvirtide), is now in clinical use. T-20 is a 36–amino acid, gp41 HR2-derived peptide that inhibits HIV-1 replication both *in vitro* and in infected patients.^{393,419} This peptide interacts directly with HR1 during the conformational changes that take place after CD4 binding. The interaction of T-20 with gp41 prevents six-helix-bundle formation, thereby blocking fusion. Resistance to T-20 arises both *in vitro* and in patients, primarily through mutations in HR1.⁶³⁰ Inhibitors that block gp120 binding to CD4 are being tested, and a number of CCR5 and CXCR4 antagonists are under development. Although CXCR4 knockout mice display a range of severe defects in hematopoiesis, central nervous system development, and gastrointestinal tract vascularization,^{739,864} no observable negative consequences of absent CCR5 function are evident in individuals homozygous for the CCR5/Δ32 mutation. Furthermore, in 2009, it was reported that a patient was apparently cured of HIV-1 infection following transplantation

of stem cells from a CCR5/ Δ 32 homozygous individual.³⁴¹ These observations suggest that inhibitors targeting CCR5 should be well tolerated. One CCR5-based inhibitor, maraviroc, is currently approved for clinical use in patients harboring R5-tropic strains of HIV-1 (for review see⁵⁸³). Maraviroc is thought to function by binding extracellular domains of CCR5 and inducing an allosteric change in CCR5 conformation that prevents gp120 binding.²¹¹ Resistance to maraviroc can arise in culture by acquisition of gp120 V3 loop mutations that allow HIV-1 to utilize the drug-bound co-receptor.⁸⁰⁰ In patients, CCR5 inhibitor resistance typically results from selection for CXCR4 strains that were present at low levels prior to the initiation of therapy.⁵³³ In addition to use of small-molecule co-receptor antagonists like maraviroc, strategies aimed at knocking down CCR5 expression in HIV-1-infected individuals are being contemplated. A strategy currently under development involves the use of zinc-finger nucleases that disrupt the CCR5 gene (for review see 102).

Reverse Transcription

By definition, retroviruses possess the ability to convert their single-stranded RNA genomes into double-stranded DNA during the early stages of the infection process.^{31,747} The enzyme that catalyzes this reaction is RT, in conjunction with its associated ribonuclease H (RNaseH) activity. Retroviral RTs have two enzymatic centers: (a) a DNA polymerase that can copy either RNA templates (for “minus-strand” DNA synthesis) or DNA templates (for second- or “plus-strand” DNA synthesis) and (b) RNaseH (for the degradation of the tRNA primer and genomic RNA present in DNA-RNA hybrid intermediates). RT was the first viral protein targeted by antiretroviral therapy, and RT inhibitors remain central to the treatment of HIV-infected patients (for reviews see^{337,703}).

Uncoating occurs after membrane fusion and entry of the viral nucleoprotein complex into the cytosol, giving rise to the reverse transcription complex (RTC). This multiprotein complex is composed not only of RNA and RT but also CA, NC, IN, and Vpr. While it was initially proposed that most if not all of the CA protein was lost from the RTC during uncoating, a variety of observations, including the fact that CA is the target for host restriction factors that disrupt reverse transcription (see later), support the hypothesis that at least some CA protein is retained in this complex. Recent findings suggest that uncoating and reverse transcription are linked; in the presence of an inhibitor of reverse transcription, uncoating is significantly delayed.³³⁸

The retroviral genome is packaged into the virion as two copies of single-stranded RNA. As discussed earlier, the two RNAs are held together in part by the DIS near their 5′ ends (see Fig. 49.7). Although each retroviral particle carries two strands of RNA, it appears that only one provirus is formed per virion.³³⁰ Retroviruses are therefore referred to as *pseudodiploid*. As with most other DNA polymerases, RT is dependent on the 3′-OH group of an RNA or DNA primer to initiate polymerization. Retroviruses use specific tRNAs (tRNA^{Lys3} in the case of HIV-1) to initiate DNA synthesis. The mechanism of tRNA selection and placement on the template is complex, involving interactions with RT and NC as well as with the 18-nt pbs near the 5′ end of the viral genome (see Fig. 49.7).

Reverse transcription of the retroviral RNA genome to a double-stranded DNA copy takes place after viral entry into the target cell and proceeds via a series of steps that are outlined

briefly here (see e-Fig. 49.2A). This is also described in Figure 47.7 of Chapter 47.

1. Minus-strand DNA synthesis is initiated from the 3′-OH of the tRNA bound to the pbs. DNA synthesis then proceeds to the 5′ end of the genome.
2. RNaseH digests the RNA portion of the newly formed RNA-DNA hybrid, freeing the resulting short, single-stranded DNA fragment (known as the minus-strand strong-stop DNA).
3. The minus-strand strong-stop DNA is transferred to the 3′ end of the genome, where it hybridizes by virtue of a short region of homology (the “repeated” or R region) present at both 5′ and 3′ ends of the RNA genome.
4. Minus-strand synthesis, accompanied by RNaseH-mediated degradation of the RNA in the resulting RNA-DNA hybrid, continues to the pbs at the 5′ end of the genome.
5. Fragments of RNA that were not removed by RNaseH serve as primers for plus-strand synthesis. The major site of plus-strand priming is the PPT (see e-Fig. 49.2A, top); however, residual RNA fragments that remain hybridized to regions outside the PPT can also be used for priming plus-strand synthesis. In the case of HIV-1, one such region, known as the central PPT, appears to be particularly important in this regard.¹¹⁴
6. After plus-strand synthesis copies a portion of the tRNA primer, RNaseH removes the tRNA. This exposes the pbs at the 3′ end of the plus-strand DNA, allowing the plus-strand DNA to hybridize with the homologous region at the 3′ end of the minus-strand DNA (*second-strand transfer*).
7. Plus- and minus-strand syntheses proceed to completion. Plus-strand synthesis terminates at the end of the minus strand and, for HIV-1, at a sequence known as the central termination signal (CTS).¹¹⁵ The position of the central PPT upstream of the CTS results in the displacement of approximately 100 nt of plus-strand DNA and the formation of a triplex DNA structure. It has been suggested that this triplex, or *DNA flap* structure, plays a role in nuclear import of the viral PIC,⁸⁴⁶ though this has been controversial. The final product of reverse transcription is a double-stranded DNA molecule capable of serving as the substrate for integration.

In addition to providing an essential function in the virus life cycle, the enzymatic activity of RT is routinely used in the laboratory to quantitatively monitor levels of progeny virions present in the supernatant of infected cultures and to elucidate the molecular details of virus replication. Also, the detection of viral DNA postinfection by real-time polymerase chain reaction (PCR) provides one of the most reliable methods to date for detecting entry and postentry steps in the virus replication cycle. Once inside the nucleus, some double-stranded viral DNA is ligated to generate circular forms; although these circular DNA products do not integrate, their formation is often used to monitor nuclear import (see later).

The mature HIV-1 RT holoenzyme is a heterodimer of 66- and 51-kD subunits. The 51-kD subunit (p51) is derived from the 66-kD (p66) subunit or some larger precursor by proteolytic removal of the C-terminal 15-kD fragment of p66 by PR (Fig. 49.6). The structure of HIV-1 RT has been determined by x-ray crystallography in a number of studies. The enzyme has been crystallized in several contexts: (a) unliganded,⁶³³ (b) bound to

FIGURE 49.13. Ribbon diagrams of the p66 (left) and p51 (right) reverse transcriptase (RT) subunits. Polymerase active site and fingers, palm, thumb, and connection subdomains are shown. (Modified by Kalyas Das and Eddy Arnold from Jacobo-Molina A, Ding J, Nanni RG, et al. Crystal structure of human immunodeficiency virus type 1 reverse transcriptase complexed with double-stranded DNA at 3.0 Å resolution shows bent DNA. *Proc Natl Acad Sci U S A* 1993;90:6320–6324.)

a short DNA duplex and the Fab portion of an anti-RT antibody,³⁵⁴ (c) covalently linked to a complex of primer/template and deoxyribonucleotide triphosphate (dNTP),³³² and (d) bound to an RNA-DNA duplex.⁶⁵⁵ A number of structures are also available for RT bound to nonnucleoside RT inhibitors (NNRTIs). The crystal structure of HIV-1 RT reveals that the p66 and p51 subunits are folded into similar subdomains, but these subdomains are arranged quite differently in p66 and p51. The p66 subunit can be visualized as a right hand, with the polymerase active site within the palm, and a deep template-binding cleft formed by the palm, fingers, and thumb subdomains³⁵⁵ (Fig. 49.13 and 49.14). The polymerase domain is linked to RNaseH by the connection subdomain. The active site, located in the palm, contains three critical Asp residues (Asp-110, Asp-185, and Asp-186) in close proximity, and two coordinated Mg^{2+} ions. Mutation of these Asp residues abolishes the polymerase activity of RT. The orientation of the three active-site Asp residues is similar to that observed in other DNA polymerases (e.g., the Klenow fragment of *Escherichia coli* DNA Pol I).²² The p51 subunit appears to play a structural role and does not form a polymerizing cleft; Asp-110, Asp-185, and Asp-186 of p51 are buried within the subunit. Approximately 18 bp of the primer/template duplex lie in the nucleic acid-binding cleft, stretching from the polymerase to the RNaseH active sites. In the RT–primer/template–dNTP structure,³³² the

presence of a dideoxynucleotide (ddNTP) at the 3′ end of the primer allows visualization of the catalytic complex blocked just prior to attack on the incoming dNTP. Comparison with previously obtained structures suggests a model whereby the fingers close in to trap the template and dNTP prior to nucleophilic attack of the 3′-OH of the primer on the incoming dNTP. After the addition of the incoming dNTP to the growing chain, the fingers adopt a more open configuration, thereby releasing the pyrophosphate and enabling RT to bind the next dNTP. HIV-1 RNaseH, whose structure has been determined by x-ray crystallography, displays a global folding similar to that of *E. coli* RNaseH.¹⁶⁹ The structure of human RNaseH1 bound to an RNA-DNA hybrid has allowed the modeling of HIV-1 RT RNaseH complexed with its substrate.⁵⁶⁶

The high rate of variation among HIV-1 populations poses one of the fundamental challenges to effectively controlling this pathogen. Highly variable virus populations are largely a consequence of rapid virus replication rates, coupled with the error-prone nature of RT (which lacks a proofreading function) and frequent template switching during reverse transcription¹⁴¹ (for review see⁷³³). Cell-free error rates for purified RTs have been determined,^{38,616,631} as have *in vivo* retrovirus mutation rates.^{2,192,491,585,586} Errors during retrovirus replication are also likely to be introduced by the cellular DNA-dependent RNA Pol II during transcription of the viral RNA. The cell-free error

FIGURE 49.14. Human immunodeficiency virus 1 (HIV-1) reverse transcriptase (RT) bound to an RNA/DNA template/primer. (Modified by Karen Kirby and Stefan Sarafianos from Singh K, Marchand B, Kirby KA, et al. Structural aspects of drug resistance and inhibition of HIV-1 reverse transcriptase. *Viruses* 2010;2:606–638.)

rate measured for HIV-1 RT is more than 10-fold higher than the mutation rate, suggesting that the *in vitro* reaction lacks factor(s) that increase fidelity.⁴⁹¹ The total HIV-1 *in vivo* mutation rate (a composite of substitutions, frameshifts, simple deletions, and deletions with insertions) was measured at ~ 1 to 3×10^{-5} per cycle of replication.^{2,491}

As discussed earlier, retroviral particles contain two copies of single-stranded RNA. During reverse transcription, RT frequently switches from one template to the other; this occurs on the order of ~ 30 times per infection event.³⁴ RT also undergoes intramolecular jumps.⁵⁸⁴ Intramolecular jumps lead to mutations (e.g., deletions, insertions, and duplications), whereas intermolecular jumps generate recombinants if the two packaged RNAs are not genetically identical.³²⁹ The intermolecular template switches that lead to recombination can occur when RT encounters a break in the RNA during polymerization—the so-called forced copy choice model.¹⁴² Jumps during minus-strand synthesis can occur in the absence of strand breaks,³⁷¹ and the stability of RT association with template is influenced by the balance between the enzyme's RNaseH activity and polymerase activity—the “dynamic copy-choice” model.³⁴² The impact of high rates of recombination and high replication rates on HIV-1 populations is substantial. As noted earlier, a significant percentage ($\sim 20\%$ ³¹²) of sequenced virus isolates are intersubtype recombinants, and recombinants constitute the predominant strains currently circulating in certain parts of the world. Recombination also provides a mechanism for the rapid generation of multiple-drug-resistant HIV-1 variants.

RT has long been a target in the search for antiviral compounds. RT inhibitors are now routinely administered to AIDS patients, usually in combination with PR and, more recently, IN inhibitors. There are two major classes of drugs that block reverse transcription: nucleoside RT inhibitors (NRTIs) and NNRTIs. Examples of NRTIs include AZT (zidovudine); 2'-deoxy-3'-thiacytidine (3TC or lamivudine); 2',3' dideoxyinosine (ddI or didanosine); and 2',3' dideoxycytidine (ddC or zalcitabine). NNRTIs include nevirapine, efavirenz, and delavirdine. NRTIs are nucleotide mimics that lack the 3'-OH and thus act as chain terminators upon incorporation into DNA, whereas the NNRTIs inhibit DNA polymerization by binding a small hydrophobic pocket near the RT active site and inducing a change in the structure of RT that blocks DNA synthesis.⁴⁰¹ Resistance to RT inhibitors often develops in patients as viral variants arise encoding mutant forms of RT that are no longer blocked by the inhibitors (for review see⁶⁵⁶). Resistance to NRTIs generally takes place by one of two mechanisms: (a) resistant RTs acquire the ability to selectively incorporate natural dNTPs but exclude the NRTI, or (b) mutant RTs incorporate the NRTI but subsequently excise it from the terminated primer. Resistance to NNRTIs occurs when mutations in RT interfere with the binding of the drug to the enzyme by disrupting key drug-enzyme interactions, changing the shape of the NNRTI binding pocket, or preventing entry of the drug into the binding pocket.⁶⁵⁷ Efforts continue to develop new NRTIs that are more difficult for drug-resistant RTs to exclude, and it may ultimately be possible to develop compounds that interfere with NRTI excision. NNRTIs with increased conformational flexibility (“wiggling and jiggling”) may also be more effective and more difficult for HIV-1 to evade if the flexible inhibitor can still bind to the altered pocket in the resistant RTs.^{162,163} Finally, a significant effort has been directed toward

developing inhibitors that target the RNaseH activity of the enzyme.

Postentry Blocks to Lentivirus Infection

TRIM5 α and Family Members

While retroviruses have evolved ingenious strategies to usurp host cell machinery to facilitate their replication, they have also been forced to counter host cell defenses aimed at restricting virus infection. Decades ago, it was discovered that cells from mice of specific genetic backgrounds express dominant factors that block infection by certain subtypes of MLV. For example, the Friend virus susceptibility-1 (*Fv1*) allele^{452,601} encodes resistance to distinct strains of MLV; *Fv1ⁿ* confers resistance to B-tropic MLV, whereas *Fv1^b* cells cannot be efficiently infected by N-tropic MLV (N-MLV). The viral determinant of N- and B-tropism maps to a specific amino acid (residue 110) in the CA domain of Gag.⁴⁰⁶ The *Fv1* block occurs early postentry, after reverse transcription but before integration.³⁶³ Although the mechanism of *Fv1* restriction remains a puzzle, it was demonstrated in the mid-1990s that *Fv1* encodes an endogenous Gag-like protein.⁵⁶

Nonmurine cells do not harbor an *Fv1* gene.⁵⁶ However, seemingly analogous postentry restrictions have also been observed in a variety of mammalian cells. N-tropic MLV poorly infects cells from a number of mammalian species.⁷⁵⁶ HIV-1 infection is inefficient in cells derived from Old World (e.g., African green and rhesus) monkeys, whereas New World (e.g., owl and squirrel) monkey cells are poorly infected by SIV_{mac}.^{319,323,695} In these cases, infection appears to be blocked at or before reverse transcription.^{54,150,756} The host factor responsible for postentry restriction of HIV-1 in rhesus macaque cells was demonstrated to be the cytoplasmic body component TRIM5 α .⁷²⁷ Expression of rhesus TRIM5 α in human cells potently inhibits HIV-1 infection but has no effect on Moloney MLV infectivity. Conversely, knock-down of TRIM5 α expression using siRNA in rhesus cells markedly increases HIV-1 infectivity.⁷²⁷ Subsequent studies indicated that human TRIM5 α expression is necessary and sufficient to block N-MLV infection in human cells^{305,383,596,833} and that TRIM5 α derived from several New World monkey species restricts infection by SIV from macaques (SIV_{mac}) and African green monkeys (SIV_{agm}) in human cells.⁷¹³ Rhesus, African green monkey, and human TRIM5 α can also diminish infection by the nonprimate lentivirus equine infectious anemia virus (EIAV),³⁰⁵ and cow and rabbit cells express TRIM-family proteins that restrict diverse retroviruses.^{670,698}

As their name implies, TRIM proteins contain three major domains: a RING domain that possesses ubiquitin ligase activity, a B-box 2 domain, and a coiled-coil domain (Fig. 49.15). The α isoform of TRIM5 (TRIM5 α) also contains a C-terminal B30.2 or SPRY domain that is absent in other TRIM5 isoforms. This C-terminal B30.2/SPRY domain harbors the determinants responsible for the species specificity of TRIM5 α -mediated restriction to retroviral infection^{553,593,712,729,833}; a single amino acid change in the B30.2/SPRY domain of human TRIM5 α converts this protein from a weak inhibitor of HIV-1 infection to one that behaves like rhesus TRIM5 α in potently restricting HIV-1 infection.⁸³³ This specificity is mediated through direct binding between the B30.2/SPRY domain and the CA protein on the incoming RTC.^{423,450,686} Binding of TRIM5 α to CA requires both TRIM5 α dimerization and

FIGURE 49.15. Organization of TRIM5 α and TRIMCyp. The major domains—RING, B-box 2, coiled-coil, B30.2 (SPRY), and cyclophilin A (CypA)—are shown. Gag-binding determinants of TRIM5 α and TRIMCyp reside in the B30.2 (SPRY) and CypA domains, respectively.

higher-order multimerization.^{423,450} The higher-order multimers have been reported to be hexameric,^{249,559} an observation that is likely relevant to the mechanism of TRIM5 restriction (see later). The importance of TRIM5 α in combating retroviral infections is supported by the finding that the CA-binding B30.2/SPRY domain in TRIM5 α has undergone positive selection during primate evolution.^{362,666,712}

In owl monkey cells, HIV-1 infection is highly inefficient but is significantly enhanced by disrupting the interaction between CA and the cellular protein cyclophilin A (CypA) (see section on Capsid). This observation suggested a link between CA–CypA binding and postentry restriction. The basis for this link was revealed when it was discovered that owl monkey cells express a form of TRIM5 α in which the C-terminal B30.2/SPRY domain has been replaced by CypA^{564,667} (Fig. 49.15). This unusual TRIM5 variant, designated TRIMCyp, restricts HIV-1 infection through a direct binding between the CypA portion of TRIMCyp and CA of the incoming particle. Thus, the ability of TRIMCyp to restrict HIV-1 infectivity in owl monkey cells is eliminated by mutations in the cyclophilin-binding domain of CA or by treating the infected cells with drugs like cyclosporine A that block the CA–cyclophilin interaction.^{564,667} Interestingly, TRIMCyp has arisen independently in several species of macaque.^{83,775,806}

TRIM family proteins assemble into cytosolic complexes often referred to as “cytoplasmic bodies.”⁶²⁴ Although pre-existing TRIM5 α or TRIMCyp cytoplasmic bodies are not required for restriction of retroviral infection,^{593,711} microscopic examination of cells overexpressing rhesus TRIM5 α early after HIV-1 infection revealed a co-localization between TRIM5 α -induced cytoplasmic bodies and viral RTCs.¹⁰⁰ Several lines of evidence support a model whereby binding of TRIM5 α or TRIMCyp to CA on the incoming RTC leads to a destabilization of the RTC and, consequently, a block to reverse transcription: (a) TRIM5 α appears to accelerate CA uncoating early postinfection in the context of either HIV-1 or N-MLV.⁷²⁸ (b) Incubation of *in vitro*-assembled core-like CA complexes with cell lysates containing TRIM5 α or TRIMCyp disrupts the assembled structures.⁶⁵ (c) Treatment of infected cells with proteasome inhibitors reverses the ability of TRIM5 α to prevent viral DNA synthesis, suggesting that TRIM5 α induces the degradation of RTCs in the proteasome.⁸¹⁷ Although proteasome inhibitors rescue the TRIM-induced defect in DNA synthesis, they do not rescue virus infectivity, suggesting a two-step mechanism of action.⁸¹⁷ (d) TRIM5 α itself undergoes proteasome-dependent degradation after exposure of cells to restriction-sensitive virus.⁶³⁶

Recent structural studies have shed light on the mechanism of action of TRIM5 α and TRIMCyp. A rhesus TRIM5 α derivative was shown to assemble *in vitro* into a two-dimensional paracrystalline hexagonal lattice.²⁴⁹ Although assembly could

occur spontaneously, it was greatly facilitated by the presence of hexagonal arrays of *in vitro*-assembled CA. These findings suggest that restricting TRIM proteins assemble on top of incoming CA hexamers, thereby leading to their disassembly and degradation. Consistent with this model, a fragment of rhesus TRIM5 α composed of the coiled-coil and B30.2/SPRY domain was shown to bind HIV-1 CA assemblies or virus-derived cores *in vitro* and induce their disassembly from an extended CA hexameric lattice to individual hexamers.⁸⁵² Binding of the CA lattice by TRIM5 α not only results in CA lattice disassembly and direct antiviral restriction but also contributes to the innate immune response against retroviral infection. Pertel and colleagues⁵⁹⁷ demonstrated that CA lattice recognition by TRIM5 α leads to the generation of free polyubiquitin chains by the ubiquitin-conjugating enzyme UBC13-UEV1A; these polyubiquitin chains in turn activate innate immune signaling through the TAK1 kinase complex.

APOBEC3G and Family Members

While lentiviral *gag* genes apparently evolved to avoid restriction by TRIM5 α and other TRIM family members, another potent suppressor of lentiviral infection drove the evolution of the lentiviral *vif* (virus infectivity factor) gene. The presence of *vif* is a highly conserved feature among lentiviruses; a *vif* product is encoded by all lentiviruses except ELAV. Soon after the discovery of the *vif* gene,^{221,706,724} it was noted that the requirement for Vif is strongly producer-cell dependent. Thus, certain cell lines (e.g., 293T, HeLa, COS, SupT1, CEM-SS, and Jurkat) are “permissive” for *vif*-defective mutants, whereas others, including primary lymphocytes, MDMs, and some T-cell lines, are “non-permissive.” This observation suggested that a host cell factor in the virus-producing cell plays a role in Vif function. Experiments performed with fusions between permissive and nonpermissive cells indicated the existence of a dominant inhibitory factor whose antiviral activity is countered by Vif.^{474,702} A major breakthrough came with the discovery that APOBEC3G (apolipoprotein B mRNA-editing enzyme, catalytic polypeptide-like 3G) is the host factor whose antiviral activity is neutralized by Vif. This finding led to a flurry of studies that have at least partially elucidated the mechanism by which APOBEC3G inhibits HIV-1 replication and the molecular basis for the ability of Vif to overcome this inhibition¹⁵⁵ (Fig. 49.16). APOBEC3G is a member of a large family of DNA cytidine deaminases that are involved in mRNA editing and immunoglobulin gene diversification.³⁰¹ These enzymes contain one or two catalytic domains characterized by His/Cys-X-Glu-X_{23–28}-Pro-Cys-X₂-Cys motifs. In the absence of Vif, APOBEC3G is incorporated into HIV-1 virions in the producer cell. In the next round of infection, the virion-associated APOBEC3G converts cytidines to uridines during minus-strand DNA synthesis.^{300,430,487,494,692,849}

FIGURE 49.16. Proposed model for inactivation of APOBEC3G by Vif. **Top:** In nonpermissive (APOBEC3G-expressing) producer cells, Vif links APOBEC3G to the cellular proteins Cul5, elongins B and C, and ring-box-1 (Rbx1) to form an Skp1-cullin F-box (SCF)-like E3 ubiquitin ligase complex, thereby inducing the proteasomal degradation of APOBEC3G and limiting its incorporation into virions. **Bottom:** In the absence of Vif, APOBEC3G is incorporated into virions. Its presence during reverse transcription in the target cell leads to impaired reverse transcription and integration and deamination of cytidines to uridines, resulting in G-to-A hypermutation. (Adapted from Freed EO. HIV-1 and the host cell: an intimate association. *Trends Microbiol* 2004;12:170–177.)

Cytidine deamination during reverse transcription leads to G-to-A hypermutation of the viral genome, disrupting viral open reading frames. APOBEC3G-induced defects in processing of the tRNA primer, plus-strand transfer during reverse transcription, and DNA integration have also been noted.⁵⁰⁸ In nonpermissive (e.g., APOBEC3G-expressing) producer cells, Vif induces the degradation of APOBEC3G, thereby counteracting its antiviral activity⁸³⁸ (for review see¹⁵⁵). The action of cellular deaminases may contribute to the prevalence of G-to-A mutations (first noted in spleen necrosis virus⁵⁸⁶ and observed in some HIV-1 sequences *in vivo*^{357,771}). Some of the antiviral activity of APOBEC3G has been reported to be independent of deamination activity of the protein, particularly at high expression levels.⁴⁸¹ While hypermutation is clearly disadvantageous to HIV-1 replication, low levels of APOBEC-induced mutation may contribute to retroviral variation and as such could be beneficial to the virus.⁶⁵¹

Vif induces the degradation of APOBEC3G through the ubiquitin-proteasome pathway by interacting with the cellular proteins Cul5, elongins B and C, and ring-box-1 (Rbx1) to form an Skp1-cullin F-box (SCF)-like E3 ubiquitin ligase complex.^{517,838} The transcription co-factor CBF-β is also recruited to this ubiquitin ligase complex³⁵⁶ (Fig. 49.16). The formation of this complex leads to the ubiquitination of APOBEC3G and its degradation in the 26S proteasome. The ability of Vif to induce the degradation of APOBEC3G is species specific; for example, HIV-1 Vif is inactive against simian APOBEC3G, and SIV_{agm} Vif is unable to block the antiviral action of human APOBEC3G. The key difference between human and simian APOBEC3G with respect to degradation

by HIV-1 Vif maps to a single residue difference between the two APOBEC3G proteins.^{71,488,676,822} Murine APOBEC3 is also readily incorporated into HIV-1 virions even in the presence of Vif, making this rodent homolog a potent inhibitor of HIV-1 replication.^{63,494}

The ability of APOBEC3G to restrict HIV-1 replication is highly dependent on its incorporation into virions. APOBEC3G incorporation is rather promiscuous: the human protein can be packaged into, and inhibit, diverse retroviruses, including SIVs, EIAV, and MLV.^{245,300,487,494} Because these viruses are highly divergent at the protein sequence level, APOBEC3G likely gains access to virions through a highly conserved structural element or by binding to molecules present in all retroviral particles (e.g., RNA). Considering that APOBEC3G acts on the viral nucleic acid during reverse transcription, it presumably must associate with the viral core³⁹¹ and ultimately with the RTC. Finally, it is reasonable to assume that APOBEC3G is incorporated through interaction with a viral element that is essential for replication; otherwise, HIV-1 could readily escape APOBEC3G restriction simply by mutating the APOBEC3G binding site without the need for acquiring a novel protein (Vif) to counter APOBEC3G activity. Several studies have focused on the mechanism by which APOBEC3G is packaged into particles, in some cases with discordant results. Some investigators have observed a direct binding between APOBEC3G and Gag, in particular the N-terminal portion of NC.^{11,111,471,669,845} Using a highly sensitive enzymatic assay to measure APOBEC3G levels in virions, others have not observed a requirement for NC in APOBEC3G incorporation.⁷³⁴ Taken together, it appears that although genomic RNA is not absolutely required,^{111,471,734,845}

RNA (viral or cellular)—perhaps in a complex with NC—performs a central function in APOBEC3G packaging. Because RNA encapsidation plays critical roles in particle assembly and virus replication, an RNA-mediated mode of incorporation would be difficult for HIV-1 to escape. RNA-mediated incorporation would also explain the ability of APOBEC3G to gain entry into highly divergent retroviruses.

Humans encode 11 APOBEC family members, with the APOBEC3 genes (APOBEC3A to H) being the most numerous.³⁰¹ Although APOBEC3G was originally identified as the cellular restriction factor that is inactivated by Vif,⁶⁹² other APOBECs also display antiviral properties. Most notably, APOBEC3F inhibits HIV-1 replication, and, like APOBEC3G, its activity is suppressed by Vif.^{63,451,456,801,854} It thus appears that Vif evolved to counter both APOBEC3G and APOBEC3F. APOBEC3B also inhibits HIV-1 infectivity, but, unlike APOBEC3G and APOBEC3F, it is resistant to degradation by Vif.^{63,188} The biological implications of APOBEC3B's antiviral activity are unclear, because this APOBEC family member may not be expressed in most primary human tissues.^{63,188}

Some Vif-negative retroviruses have evolved distinct mechanism(s) for evading restriction by cellular cytidine deaminase. HTLV-1 appears to counter APOBEC3G restriction through a C-terminal extension of its NC domain that blocks packaging of APOBEC3G into particles.¹⁸³ Although MLV infection is inhibited by human APOBEC3G, it is insensitive to all other human APOBEC family members and is resistant to murine APOBEC3 *in vitro*.^{63,189} However, *in vivo*, disruption of the murine *APOBEC3* gene leads to enhanced MLV replication and MLV-induced tumor induction.⁴⁶³ Knockout of murine APOBEC3 also increases the susceptibility of mice to mouse mammary tumor virus infection.⁵⁷⁰ Horses encode six APOBEC3 proteins, one of which is capable of inhibiting HIV-1 replication. Despite efficient packaging into virions, this APOBEC3 does not inhibit ELAV infectivity, suggesting a mechanism of APOBEC evasion that does not rely on virion exclusion.⁷⁰

The interplay between Vif and APOBEC cytidine deaminases offers novel possibilities for antiretroviral therapy. For example, disrupting the binding between Vif and APOBECs with small-molecule inhibitors would activate the antiviral activity of the cellular enzymes. Interfering with Vif-mediated APOBEC degradation could also theoretically be achieved with proteasome inhibitors (which also block virus budding), by functional disruption of the ubiquitin-conjugating enzymes or ubiquitin ligases specifically responsible for APOBEC ubiquitination, or by blocking the interaction of APOBECs with the SCF-like E3 ubiquitin ligase complex. Some initial progress toward targeting APOBEC and Vif has been made; inhibitors that prevent Vif-mediated APOBEC3G degradation¹¹² or that induce the degradation of Vif itself⁵⁵⁵ have been reported.

SAMHD1

As mentioned previously, recent studies have demonstrated that the host protein SAMHD1 restricts an early step in lentiviral infection in myeloid cells and is counteracted by the accessory protein Vpx. This topic will be discussed in more detail later in the section on Vpx.

Nuclear Import

Most retroviral genomes gain access to host cell chromosomal DNA during progression of the target cell through the cell

cycle.^{444,634} These retroviruses are therefore unable to efficiently infect noncycling cells. In contrast, lentiviruses, including HIV-1, are able to productively infect nondividing cells (e.g., macrophages). During the events leading to its integration in the nucleus, the newly synthesized viral DNA remains associated with the PIC. This complex, which is composed of both viral and cellular proteins,^{79,87} must presumably possess the ability to cross the nuclear membrane during interphase to access the host cell genome. Because the HIV-1 PIC—estimated to be ~56 nm in diameter⁵²³—is much larger than the passive diffusion limit for nuclear pores (~9 nm),⁵⁰⁵ it has long been assumed that the PIC must harbor determinants that promote active nuclear import. Initially, it was proposed that MA contains the determinants of PIC nuclear import^{90,777}; however, this model was not validated.^{226,230,232} Subsequent findings implicated Vpr in nuclear import (see section on Vpr). Numerous studies have observed that IN localizes to the nucleus, giving rise to the hypothesis that IN regulates PIC transfer across the nuclear membrane (e.g.,⁷⁸). This model has also been controversial, because mutations that disrupt the nuclear import of IN can cause defects in multiple aspects of IN function.^{347,467} It has also been proposed that a *cis*-acting, centrally located, triple-stranded DNA structure described earlier and known as the *central DNA flap*, which is a product of lentiviral reverse transcription (see section on Reverse Transcription), promotes nuclear import of the PIC.⁸⁴⁶ Although inclusion of the central flap improves the infectivity of lentiviral vectors, there is some disagreement as to whether this sequence is required in the context of replication-competent, full-length HIV-1 molecular clones.^{19,197,454} An HIV-1 chimera-containing MLV IN and lacking all other proposed determinants of nuclear import (e.g., MA, Vpr, and the central DNA flap) retains the ability to infect nondividing cells,⁸²⁵ indicating that none of these elements is critical for HIV-1 nuclear import.

Although the viral determinants of nuclear import, and the mechanism by which they function, remain to be clarified, there is compelling evidence for a connection between CA and nuclear import. It was initially believed that HIV-1 CA is lost from the reverse transcription complex during uncoating; it now appears, however, that a significant amount of CA remains associated with this complex.^{21,187,512} Analysis of chimeras between MLV (which is unable to infect nondividing cells) and HIV-1 (which can infect nondividing cells) revealed that the ability to infect nondividing cells maps to CA.⁸²³ Furthermore, mutations in CA can impose on HIV-1 infection a requirement for cell cycle progression⁸²⁶ and can inhibit nuclear import.¹⁸⁷

As mentioned earlier, several genome-wide RNA interference (RNAi) screens have identified a large number of host factors that are putatively required for HIV-1 infection.^{82,404,857} Among these are nuclear pore proteins and karyopherins—including transportin 3 (TNPO3; also known as TRN-SR2), NUP153, and NUP358/RanBP2—that could play a role in PIC transfer across the nuclear pore. TNPO3 was shown to bind HIV-1 IN and promote PIC nuclear import.¹³¹ Subsequent work⁴¹⁰ confirmed a role for TNPO3 in HIV-1 infection and demonstrated that most lentiviruses showed a requirement for TNPO3 (feline immunodeficiency virus [FIV] being the exception) but that other retroviruses (e.g., RSV and MLV) did not. This study, however, failed to observe a role for IN–TNPO3 binding in the ability of TNPO3 to promote infection. Rather, the use of the HIV-1/MLV chimeras mentioned earlier

pointed to a role for CA in determining TNPO3 dependency.⁴¹⁰ NUP358/RanBP2 bears a cyclophilin domain that has been reported to bind directly to CA; this interaction promotes PIC nuclear import and also influences integration site preference.⁶⁷¹

In a screen designed to identify dominant factors that interfere with HIV-1 infection, a C-terminally truncated form of cleavage and polyadenylation factor 6 (CPSF6) was shown to block an early step in the HIV-1 infection process—specifically nuclear import—but had no effect on MLV infectivity.⁴³² Selection experiments gave rise to a resistant mutant that, intriguingly, contained a single amino acid change in CA (N74D). This N74D CA mutant was not only resistant to inhibition by the truncated CPSF6 but also displayed an altered requirement for karyopherins and nuclear pore factors. For example, wild-type (WT) HIV-1 infection was inhibited by depletion of TNPO3, RanBP2, and NUP153, but infectivity of the N74D mutant was relatively unaffected.^{432,504} Conversely, N74D infection was more sensitive than WT to depletion of nuclear pore proteins NUP85 and NUP155. These data again support a role for CA in PIC nuclear import and demonstrate that CA regulates HIV's utilization of nuclear transport and pore components. CPSF6 is typically localized to the nucleus and overexpression of the full-length, nuclear form has little effect on HIV-1 infection.⁴³² The truncated form that inhibits HIV-1 infection lacks the CPSF6 nuclear localization signal (NLS) and is thus localized to the cytosol. Thus, the shift in CPSF6 localization from nucleus to cytosol may play a key role in its inhibitory activity. Consistent with this model, CPSF6 becomes cytosolic in TNPO3-depleted

cells.⁴³³ Kewalramani⁴³³ showed that in TNPO3-depleted cells CPSF6 becomes cytosolic. Furthermore, CPSF6 depletion reverses the inhibitory effect of TNPO3 depletion. These data suggest that the effect of TNPO3 on HIV-1 is mediated through CPSF6. Because CPSF6 interacts with HIV-1 CA, it is conceivable that this protein plays a regulatory role in HIV-1 infection, potentially as a PIC uncoating or transport factor.

Integration

A distinguishing feature of retrovirus replication is the insertion of a DNA copy of the viral genome into the host cell chromosome after reverse transcription. The integrated viral DNA (the *provirus*) serves as the template for the synthesis of viral RNAs and is maintained as part of the host cell genome for the lifetime of the infected cell. Retroviral mutants deficient in the ability to integrate generally fail to establish a productive infection.

The integration of viral DNA is catalyzed by IN, a 32-kD protein generated by PR-mediated cleavage of the C-terminal portion of the HIV Gag-Pol polyprotein (see Fig. 49.6). The steps in the integration process were originally elucidated in studies using MLV,^{87,242} but these findings apply to HIV as well. In all retroviral systems, integration proceeds in the same series of steps (Fig. 49.17):

1. 3' processing: After its assembly with the viral DNA, IN cleaves immediately downstream from the invariant nucleotide sequence CA, typically removing two nucleotides

FIGURE 49.17. Schematic depiction of the integration process. Details are provided in the text.

from the 3' termini of both strands of full-length, linear viral DNA, generating a preintegration substrate with 3' recessed ends.

2. DNA strand transfer: In the nucleus, IN catalyzes a staggered cleavage in the cellular target DNA. The 3' recessed ends of viral DNA are joined to the 5' "overhanging" termini of the cleaved cellular DNA.
3. Gap repair: The cellular repair machinery fills the gap, thereby completing the integration process.^{87,242,644} All integrated proviruses terminate with dinucleotides 5'-TG and CA-3', whereas different genera yield different-sized flanking duplications based on the spacing of the staggered chromosomal DNA cut; the lentiviral duplication is 5 bp. In addition to the linear, double-stranded viral DNA that serves as the substrate for integration, two types of circular DNA are formed in the nucleus: 1-LTR circles and 2-LTR circles. Although these circular DNAs are not substrates for integration, they provide useful markers for nuclear import of the viral DNA, as their formation requires enzymatic machinery present predominantly in the nucleus.

Our understanding of the chemistry of the retroviral integration reaction was greatly assisted by the development of *in vitro* integration assays. Purified IN, expressed in *E. coli*, can carry out 3' processing and strand transfer reactions when combined with short synthetic oligonucleotides that mimic the viral DNA ends and a divalent metal ion (Mg^{2+} or Mn^{2+}).^{151,379} Using such systems, IN also catalyzes a reaction known as disintegration, which in essence is the strand transfer reaction in reverse.¹²⁸ While disintegration may not reflect a physiologically relevant activity of IN, it nevertheless has been useful in understanding the biochemistry of integration. Initial studies observed that the predominant product in *in vitro* assays using purified HIV-1 IN was a single end joined to one strand of the target, rather than the more physiologically relevant product in which both ends are integrated into the target (*concerted* or *full-site* integration).

Retroviral IN proteins are composed of three structurally and functionally distinct domains: an N-terminal zinc-binding domain (NTD), a catalytic core domain (CCD), and a C-terminal domain (CTD) (Fig. 49.18). Problems with low solubility and propensity to aggregate hindered progress in defining the structure of the IN holoenzyme in its active (tetrameric) state. However, the structures of all three domains independently and in various combinations were solved by x-ray crystallography or NMR methods. The NMR structure of the NTD⁹⁶ revealed three helical bundles with a zinc coordinated by invariant amino acids His-12, His-16, Cys-40, and Cys-43. The structure of the NTD is reminiscent of helical DNA-binding proteins that contain a helix-turn-helix motif.

FIGURE 49.18. Schematic representation of an integrase (IN) monomer. The three major structural domains—the N-terminal domain (NTD), catalytic core domain (CCD), and C-terminal domain (CTD)—are shown. The catalytic triad Asp-64, Asp-116, and Glu-152 is represented as D-D-E.

Initially, poor solubility hampered efforts to solve the structure of the CCD. However, attempts at crystallography were successful when a mutation was identified that greatly increased solubility without disrupting *in vitro* catalytic activity.¹⁹⁸ Each monomer of the core domain is composed of a five-stranded β -sheet flanked by helices; this structure bears striking resemblance to that of other polynucleotidyl transferases including RNaseH and the bacteriophage MuA transposase.^{198,626} Three highly conserved residues are found in analogous positions at the catalytic center of these enzymes; in HIV-1 IN, these residues are Asp-64, Asp-116, and Glu-152—often referred to as the D,D-35-E motif (Fig. 49.18). Mutations in this catalytic triad block HIV-1 IN function both *in vivo* and *in vitro*. The IN CTD, whose structure was initially solved by NMR,^{200,461} adopts a five-stranded β -barrel folding topology reminiscent of Src homology 3 (SH3) domains. The crystal structure of an HIV-1 NTD-CCD IN fragment⁷⁸⁹ revealed a dimer of dimers, with two inner monomers and two outer monomers, with an extensive intermolecular NTD-CTD interface that provided a preview of the interface evident in the structure of the full retroviral tetramer.

A breakthrough in IN structural biology took place in 2010 with the realization that the IN of prototype foamy virus (PFV) is highly soluble and capable of concerted integration *in vitro* with short DNA substrates.⁷⁶³ Although divergent at the overall amino acid sequence level, HIV-1 and PFV IN are structurally conserved. The IN tetramer bound to DNA oligonucleotides that mimic the viral DNA ends—which together form the active nucleoprotein complex referred to as the “intasome”—was crystallized and the structure solved.²⁹⁴ This structure revealed that two monomers in the tetramer interact at a dimer interface and are responsible for all contacts with the DNA substrate; the other two monomers are on the outside of the complex and do not interact with each other or with DNA (Fig. 49.19). The residues of the catalytic triad (D,D-35-E) of the inner monomers are oriented close to the 3'-OH of the viral DNA ends. Two metal ions are coordinated at the active site by the residues of the catalytic triad. The addition of model target DNA to the intasome allowed for crystallization of a complex containing both viral and target DNAs.⁴⁷⁷ In the presence of Mg^{2+} the strand transfer reaction took place during crystallization, whereas in the absence of divalent metal ions strand transfer was blocked. This allowed capture of postcatalytic strand transfer and prestrand transfer complexes. These structures revealed that the target DNA, which binds in a cleft between the two halves of the intasome complex, adopts a highly bent conformation, allowing the well-separated intasome active sites to access the scissile phosphodiester bonds in the target DNA (Fig. 49.19). The viral (donor) DNA duplex is unpaired at the active site. Conformational changes that occur during catalysis are predicted to render the strand transfer reaction irreversible.⁴⁷⁷ Following the original publication of the structures described earlier,^{294,477} a number of additional PFV structures that contained potent inhibitors were solved (discussed later; for review see⁴⁴⁹); together these reports allowed the development of a structural model for HIV-1 integration that was validated by extensive mutational analysis.⁴⁰⁹

Although the basic mechanism by which retroviruses integrate their DNAs into the host cell genome is highly conserved, different retroviruses display clear differences in the selection of a cellular target site.⁵²⁵ For example, HIV-1 prefers to

FIGURE 49.19. Structure of the prototype foamy virus integrase (IN) tetramer in complex with viral DNA ends.

The lower image is rotated 90 degrees relative to the upper image. The outer IN chains are yellow; the inner chains are green and cyan. The reactive and nontransferred strands of the viral DNA ends are magenta and orange, respectively. Active-site carboxylates are represented as red sticks. Mn^{2+} and Zn^{2+} ions are shown as large and small gray spheres, respectively. The major IN domains (see Fig. 49.18 legend) are labeled. Note that prototype foamy virus also encodes an N-terminal extension domain (NED) not present in human immunodeficiency virus 1 (HIV-1) IN. (Reprinted from Cherepanov P, Maertens GN, Hare S. Structural insights into the retroviral DNA integration apparatus. *Curr Opin Struct Biol* 2011;21:249–256, copyright 2011, with permission from Elsevier.)

integrate in actively transcribed genes. MLV favors transcription start sites but only weakly selects active genes. ASLV displays a strong preference for neither active genes nor transcription start sites; indeed, for ASLV, high-level transcription appears to be inhibitory for integration.⁵⁰⁷ Target site selectivity, which impacts upon the development of retroviruses as vehicles for gene therapy, is likely influenced by interactions between IN or other components of the PIC and chromatin-associated host factors. Several cellular proteins have been studied extensively for their contribution to integration and target site selection. The most important among these is a 75-kD, predominantly nuclear, chromatin-associated protein known as LEDGF/p75. A direct interaction between HIV-1 IN and LEDGF/p75 was reported,^{124,204} and this protein was found to stimulate the strand transfer step of the integration reaction *in vitro*¹²⁴ and increase binding of IN to DNA.⁹³ However, early studies were discordant in terms of the effect of LEDGF/p75 depletion on HIV-1 replication.^{459,769} It soon became apparent that low levels of chromatin-bound LEDGF/p75 were sufficient to promote integration in cells. Near-complete knock-down of LEDGF/p75 levels⁴⁵⁸ or use of a murine LEDGF/p75 knock-out cell line⁶⁹⁷ revealed markedly reduced (but not fully abolished) HIV-1 infectivity in the absence of detectable LEDGF/p75 expression. Infectivity was also severely compromised by overexpression of the IN-binding domain (IBD) of LEDGF/p75.^{174,458} In the case of both LEDGF/p75 depletion and LEDGF/p75-IBD overexpression, infectivity was disrupted at the integration step, and the effect was specific for lentiviruses, establishing LEDGF/p75 as a cellular co-factor for lentiviral integration. Studies in which siRNA-resistant LEDGF/p75

mutants were added back to LEDGF/p75-depleted cells identified domains of LEDGF/p75 required for its activity as an integration co-factor.^{458,697,770} The observation that the LEDGF/p75-IBD and the chromatin-binding regions (the PWWP domain and AT-hook) (Fig. 49.20) were required for function supported the hypothesis that LEDGF/p75 functions to tether the PIC to target chromosomal DNA. The crystal structure of the IN-CCD and LEDGF/p75-IBD complex provided further details of the IN-LEDGF/p75 interaction.¹²³ In addition to a clear role for LEDGF/p75 in directing HIV-1 integration to transcription units, TNPO3 and the nuclear pore protein RanBP2/Nup358 have also been implicated in the targeting of HIV-1 integration. Ocwieja and colleagues⁵⁶⁷ reported that depleting these genes shifted HIV-1 integration out of gene-dense regions. In contrast, TNPO3 depletion had no effect on the targeting of MLV integration. Use of the aforementioned HIV/MLV chimeras once again mapped the requirement for TNPO3 to Gag.⁵⁶⁷

One of the notable findings to emerge from the LEDGF/p75 depletion studies is that in the absence of LEDGF/p75 expression, HIV's preference for integrating into transcriptional units is lost.^{138,697} These results are consistent with the hypothesis that the ability of LEDGF/p75 to tether lentiviral PICs to chromatin is a major determinant for target-site selection. This hypothesis in turn suggests that the targeting of lentiviral integration could be shifted out of transcription units by substituting the chromatin-binding sequences of LEDGF/p75 with chromatin-binding domains from other proteins. Indeed, the infectivity defect conferred by LEDGF/p75 depletion can be rescued with a chimeric protein bearing the LEDGF/p75 IBD

FIGURE 49.20. Model for integrase (IN)/lens epithelium-derived growth factor (LEDGF) binding to chromosomal DNA. The preintegration complex, containing an IN tetramer (yellow) and viral DNA (vDNA), is depicted in green. The IN-binding domain (IBD) of LEDGF is shown bound to the IN tetramer. The nuclear localization signal (NLS) and AT hooks (AT) are shown in complex with DNA; the PWWP domain is depicted bound to histone proteins. (Reprinted from Adamson CS, Freed EO. Novel approaches to inhibiting HIV-1 replication. *Antiviral Res* 2010;85:119–141, copyright 2010, with permission from Elsevier.)

and foreign chromatin-binding domains,⁵¹⁵ and such chimeric PIC-tethering factors are able to shift HIV-1 integration target site specificity away from actively transcribed genes.^{217,261,700} The ability to engineer such custom-designed PIC–chromatin tethering factors and control integration site specificity may have applications in lentiviral-based gene therapy. The function of LEDGF/p75 in promoting HIV-1 integration raises the possibility that the IN–LEDGF/p75 interaction could serve as a target for developing novel antiviral therapeutics. By using the IN–CCD–LEDGF/p75–IBD co-crystal structure in an *in silico* screen, Debyser and colleagues¹³² identified small-molecule “LEDGINs” (LEDGF/p75–IN inhibitors) that block the protein interaction *in vitro* and HIV-1 infection at the integration step.

Early studies showed that several classes of agents inhibit IN function *in vitro*; these included polyanions, nucleotide analogs, and DNA-binding compounds.²⁰⁹ Most of these agents are fairly nonspecific in their mode of action, and many compounds that block activity of purified IN are not inhibitory in assays using purified PICs.²¹⁰ However, di-keto acid inhibitors were found to be specific and potent inhibitors of the IN-mediated strand transfer reaction both *in vitro* and in cell-based assays.³⁰⁷ These IN strand transfer inhibitors (INSTIs) bind IN only in the presence of divalent metal and viral DNA and prevent the complex from associating with cellular (target) DNA. Although structurally diverse, INSTIs appear to have common features, including (a) a hydrophobic moiety composed of halobenzyl groups and (b) co-planar oxygen atoms presumed to chelate the metal ions in the active site.⁵⁰⁹ Work in the early 2000s showed that naphthyridine carboxamides inhibit the replication of an SHIV in rhesus macaques, setting the stage for *in vivo* use of INSTIs.³⁰⁸ Further structure-activity relationship studies led to the development of raltegravir, also known

as MK-0518 or Isentress (Merck Research Laboratories),⁷³¹ and elvitegravir (Gilead Sciences and Japan Tobacco).⁶⁵⁹ Raltegravir was approved for clinical use in HIV-infected patients by the U.S. Food and Drug Administration (FDA) in 2007 and elvitegravir was approved in 2012 (reviewed in⁵⁰⁹).

The observation that INSTIs are active against a wide variety of retroviruses,⁴⁰⁰ including PFV,⁷⁶³ allowed structures to be determined for raltegravir and elvitegravir bound to the PFV IN active site²⁹⁴; this information was subsequently extended to the HIV-1 model.⁴⁰⁹ Additional PFV structures that included highly potent second-generation INSTIs have moreover since been solved.^{295,296} These structural analyses confirmed that INSTIs chelate the metals in the enzyme active site and demonstrated that the halobenzyl moieties of the INSTI stack against the cytidine of the invariant CA dinucleotide and in doing so supplant the adenine ring and eject its associated DNA strand transfer 3'-OH nucleophile from the active site.^{294,296,409} As with other HIV inhibitors, resistance develops both *in vitro* and *in vivo*. Three major pathways of resistance have been observed for raltegravir—these involve residues N155, Q148, and Y143 (reviewed in⁵¹⁹). Secondary mutations arise at a number of additional positions. Elvitegravir treatment leads to the acquisition of mutations in IN residues T66 and S147, as well as changes associated with raltegravir resistance (at residues Q148 and N155).

Viral Gene Expression

The HIV LTR

Retroviral LTRs are generated during the process of reverse transcription and therefore exist only as “repeats” in viral DNA. During the replicative cycle, sequences mapping to the LTR serve a multitude of functions in the context of both proviral DNA and genomic RNA. First, complementary genomic RNA and minus-strand DNA sequences located in the R region mediate a critical early step of the reverse transcription reaction by forming intermolecular DNA–RNA hybrid structures (see section on Reverse Transcription) (see e-Fig. 49.2A, step 4). These hybrids link the newly synthesized DNA strand (“minus” polarity) with complementary RNA sequences at the 3' end of the same or a different genomic RNA template (“plus” polarity), thereby allowing the RT to continue its polymerizing activity and generate a full-length minus-strand DNA. Second, during the integration step of the virus life cycle, LTR elements (*att*, or attachment, sequences) located at the termini of full-length linear viral DNA molecules guide their insertion into the chromosomal DNA of host cells (see section on Integration) (e-Fig. 49.2B). Other LTR sequences, located in the context of U5 RNA sequences, have been reported to contribute, in concert with the ψ element (see Fig. 49.7), to the packaging of progeny HIV-1 RNA genomes during virus assembly (see Fig. 49.8).

In the context of integrated viral DNA, the major function of the retroviral LTR is the regulation of viral RNA synthesis. The HIV-1 transcriptional promoter and multiple regulatory elements are located within the U3 region and function in the context of the 5' LTR (Fig. 49.21). Their principal function is to recruit the RNA Pol II holoenzyme to the start site (+1) of viral RNA synthesis, also defined as the first nucleotide in the LTR R region. The recognition of the core promoter by RNA Pol II is the first step for initiating RNA synthesis. The formation of the preinitiation complex begins when the general

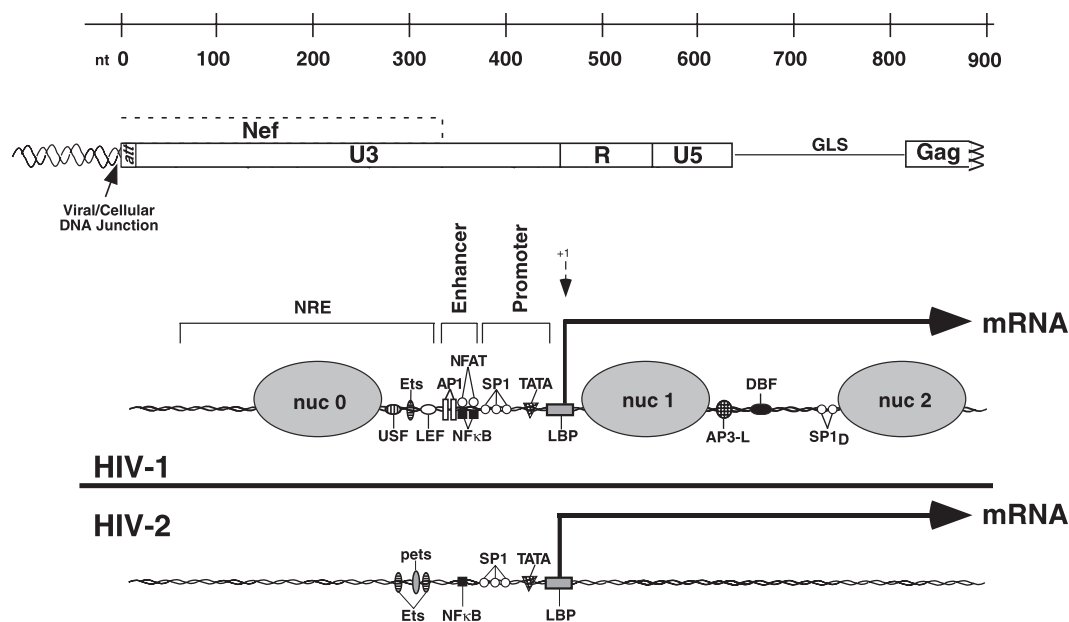

FIGURE 49.21. Fine structure of the human immunodeficiency virus type 1 (HIV-1) long terminal repeat (LTR). The HIV-1 LTR is a duplicated 630+ base-pair (bp) element located at the termini of integrated proviral DNA (as shown in Fig. 49.20A, top). A blow-up of the 5' LTR and adjacent cellular and Gag coding sequences is presented at the **top**. The HIV-1 LTR has been subdivided into three domains: the R (repeat) region is defined as a 96-nt repeat present at the 3' and 5' termini of HIV-1 genomic RNA; U5 is an 84-nt segment located immediately 3' to the R region; and U3 is a 454-nt segment situated immediately 5' to R. The portion of the *nef* gene overlapping U3 and the location of terminal attachment (*att*) sequences are shown. The 5' LTR and adjacent *gag* leader sequence (GLS) are aligned with the subdivided LTR (**middle**) to indicate functionally important binding sites for transcriptional regulatory proteins. For HIV-1, the core promoter consists of the three Sp1 binding elements and the TATA site. The two nuclear factor- κ B (NF- κ B) binding motifs, the nuclear factor of activated T cells (NFAT), and adjacent activator protein 1 (AP-1) elements compose the “enhancer” domain. The transcription start site is located at map position “+1,” which is defined as the border between U3 and R. The negative regulatory element (NRE) contains binding sites for the upstream stimulatory factor (USF) and the Ets proteins. Sequence motifs that interact with the TATA-binding protein (TBP), leader-binding protein (LBP), AP-3-like (AP3-L), DBF-1, and two downstream Sp1 elements (SP1_D) are shown. The positions of nucleosomes nuc 0, nuc 1, and nuc 2 are indicated. For HIV-2 (**bottom**), the unique binding sites for the peri-ets (pets) and E26 transforming specific (Ets) transcriptional factors are indicated.

transcription factor (GTF) TFIID binds to several core promoter elements including the TATA box, located –29 to –24 nt upstream of the transcriptional start site (Fig. 49.21). TFIID consists of the TATA box-binding protein (TBP) and 13 or 14 TBP-associated factors (TFA) that bind downstream elements including the initiator elements spanning the transcription start site. The GTF factor TFIIA then enters the complex, facilitating the binding of TFIID to the core promoter to generate a platform upon which a functional transcription complex can be assembled.

A third GTF (TFIIH), which modifies RNA Pol II allosterically and allows the transcription complex to initiate RNA polymerization and “escape” from the promoter, must also be incorporated into the RNA Pol II complex.⁴⁶⁴ TFIIH is a multicomponent transcription factor that includes a kinase activity able to phosphorylate a unique region within the largest RNA Pol II subunit, the CTD, which contains a heptad sequence (consensus YSPTSPS) that is repeated 52 times. The phosphorylated state of the CTD critically determines the functional state of Pol II. Whereas hypophosphorylated Pol II (Pol IIa) is readily recruited into the preinitiation transcription complex, the hyperphosphorylated form of the enzyme (Pol IIo) medi-

ates the elongation of nascent RNA transcripts. Three kinases, associated with the transcriptional apparatus, are known to phosphorylate the CTD. These kinases include (a) the CDK7/cyclin H subunits of the CDK-activating kinase (CAK) complex associated with TFIIF, (b) the CDK8/cyclin C component of the RNA Pol II holoenzyme, and (c) the CDK9/cyclin T subunits of the positive transcription elongation factor b (P-TEFb). Hyperphosphorylation of the CTD induces conformational changes in RNA Pol II that allow the transcription complex to clear the promoter and begin elongating nascent viral RNA molecules. These cellular kinases, which participate in transcriptional elongation, will be discussed in greater detail in the section describing the function of the HIV-1 Tat protein.

In eukaryotic cells, regulatory factors, which bind to DNA elements near the promoter, modulate the basal rate of RNA synthesis in response to physiologic cues, after the recruitment of Pol II. This process results in the more frequent assembly of stable transcription complexes that are better able to escape the promoter and generate full-length primary transcripts. The human genome encodes more than 2,500 proteins with DNA-binding domains, many of which function to regulate RNA synthesis. Binding sites for distinct transcription factors

frequently flank the promoters for cellular and viral genes. The HIV promoter contains its own ensemble of DNA elements to which transcriptional regulatory factors bind (Fig. 49.21). In the context of HIV-1 replication, distinct combinations of transcription factors may be found in the different cell types (T cells and MDMs), activated states (naïve and memory CD4+ T lymphocytes), and tissues (lymph nodes, gastrointestinal tract, and CNS) targeted by the virus. The combinatorial use of subsets of these factors will determine the efficiency of progeny virus production at these various locations and activation states. The transcription of HIV-1 and cellular genes in CD4+ T lymphocytes is highly dependent on extracellular stimuli that induce the translocation of some of these regulatory factors into the nuclear compartment. Consequently, in an infected individual, the HIV-1 LTR may have to direct viral RNA production in multiple and functionally unique micro-environments.

Traditionally, the synthesis of HIV-1 RNA has been studied by (a) transfecting LTR-driven reporter gene constructs into HeLa cells or other continuous human cell lines or (b) infecting human T-cell lines or PBMCs, collected from uninfected individuals, with HIV derived from replication-competent molecular clones. In these experiments, RNA production is monitored under basal conditions or following activation with the HIV-1 Tat protein. Studies with human PBMCs have been conducted under resting or activated conditions. The LTRs of HIV and other primate lentiviruses contain three tandemly arranged binding sites for the constitutively expressed Sp1 transcription factor; these DNA elements are situated immediately upstream of a canonical RNA Pol II TATA box (Fig. 49.21). The Sp1 and TATA elements constitute the HIV-1 core promoter and must be present for basal levels of LTR-directed RNA synthesis. Functional analyses of HIV-1 LTR-driven reporter constructs have shown that mutations of individual or pairs of the three Sp1 sites have little, if any, effect on basal or Tat-transactivated expression levels.²⁹⁹ Mutation of all three HIV-1 Sp1 sites, however, markedly reduced the response to the HIV-1 Tat protein.²⁹⁹ In the context of virus infections, the role of the Sp1 elements is cell type dependent.^{438,642} Mutations that functionally inactivated all three Sp1 motifs eliminated detectable replication in Jurkat cells and delayed progeny virus production in CEM and H9 cells but had little effect on replication in activated PBMCs.

Three transcriptional factors (NF- κ B, nuclear factor of activated T cells [NFAT], and AP-1) play major roles in regulating cellular and HIV-1 RNA synthesis in human T lymphocytes after antigen-specific/MHC-restricted signaling through the T-cell receptor-CD3 complex. The two binding sites for the NF- κ B/Rel family of transcription factors constitute the principal activatable enhancer elements in the HIV-1 LTR. The NF- κ B sites (consensus sequence: GGGRNNYYCC) are located upstream and adjacent to the Sp1-binding motifs in all HIV-1 isolates.⁵⁵² In clade E strains, a single inactivating nucleotide deletion in the upstream NF- κ B element converts it to a GA-binding protein (GABP) site, and clade C isolates carry a third NF- κ B site (Table 49.2). The LTRs of HIV-2 and SIV, while retaining the triplicated Sp1 motifs, each contain only a single NF- κ B binding site (Fig. 49.21, bottom). The mammalian NF- κ B family of proteins consists of five members: p65 (Rel A), Rel B, c-Rel, p50 (derived from the p105 precursor), and p52 (derived from the p100 precursor). All NF- κ B proteins contain a highly conserved Rel homology domain (RHD),

Adapted from van Opijnen T, Jeeninga RE, Boerlijst MC, et al. Human immunodeficiency virus type 1 subtypes have a distinct long terminal repeat that determines the replication rate in a host-cell-specific manner. *J Virol* 2004;78:3675–3683.

which is approximately 300 residues in size and located near the N-terminus. The RHD mediates DNA binding, dimerization with other NF- κ B partners, and interaction with the inhibitor protein, I κ B; it also contains a NLS. Some NF- κ B proteins, including p65, also carry a potent transcription activation domain located near their C-termini, which can promote the transcription of target genes by recruiting activating and repressing cellular transcription factors. The NF- κ B inhibitory proteins, I κ B α , - β , and - ϵ , all contain multiple 30- to 34-amino acid ankyrin motifs, which provide the interface for binding to various species of NF- κ B.

In vivo, NF- κ B is intimately involved in inflammation, cell proliferation, and apoptosis. It modulates the expression of cytokines (IL-6, IL-1 β , tumor necrosis factor- α [TNF α], GM-CSF), chemokines (IL-8, RANTES, macrophage inflammatory protein-1 α [MIP-1 α], monocyte chemoattractant protein-1 [MCP-1]), enzymes (inducible nitric oxide synthase [iNOS], cyclo-oxygenase-2 [COX-2]), and adhesion molecules (vascular cell adhesion molecule-1 [VCAM-1], ICAM-1, E-selectin) in response to the stimulation of numerous receptors involved in immune responses, including T-cell receptors, B-cell receptors, TNF receptors, CD40, and the Toll/IL-1R family.⁷³ Because the various members of the NF- κ B family are present intracellularly as dimeric molecules, a heterogeneous population of homo- and heterodimers, with different functional specificities, bind to the two NF- κ B sites present in the HIV-1 LTR. For HIV-1 gene expression, the two most important forms of NF- κ B are the p50/p50 homodimer and the p50/p65 heterodimer. The functional activity of NF- κ B is controlled by its intracellular location. p50/p65 NF- κ B molecules are sequestered in the cytoplasm as a consequence of the tight binding of unphosphorylated I κ B α to the RHD of the p65 subunit of the heterodimer. It is believed that cytoplasmic retention of the NF- κ B-I κ B α complex is due to the masking of the p65 NLS, which is also located in the RHD. Following activation of the protein kinase C pathway, phosphorylation of two I κ B N-terminal serine residues (S32 and S36) occurs. Phosphorylated I κ B is rapidly degraded as a

result of ubiquitination and proteolysis via the 26S proteasome complex; the freed p50/p65 NF- κ B is then translocated into the nucleus where it can activate multiple cellular genes including I κ B. The newly synthesized (and unphosphorylated) I κ B enters the nucleus, where it captures NF- κ B and returns it to the inducible cytoplasmic pool of NF- κ B molecules. The nucleocytoplasmic shuttling property of I κ B and the feedback loop controlling its synthesis are responsible for the transient nature of NF- κ B activity.^{73,306}

When the NF- κ B binding sites are mutagenized in the context of HIV-1 infectivity, virus replication is affected, depending on the type of mutant constructed and the endogenous levels of NF- κ B in the cells used to generate progeny virions. Deletion of both HIV-1 NF- κ B motifs resulted in modest⁶⁴² delays in peak virus production in activated human PBMCs, whereas point mutations affecting specific nucleotides in the NF- κ B recognition sequence, but not the spatial organization of the two NF- κ B elements within the HIV-1 LTR, reduced virus production more than 10-fold.¹¹⁹ The replication of HIV-1-bearing NF- κ B mutations in several human T-cell lines was found to be inversely proportional to the basal levels of NF- κ B in the particular cell line under study. It is likely that other transcription factors present in these cells can compensate for the absence of NF- κ B in these viral mutants. The simultaneous mutation of the two NF- κ B motifs and all three Sp1 sites completely abolishes HIV-1 replication,^{438,642} consistent with the demonstration that the cooperative interaction of NF- κ B and Sp1 promotes the binding of both factors to the HIV-1 LTR and induces transcriptional activation.⁵⁹⁵ A conclusion from all of these results is that NF- κ B stimulates transcription from the HIV-1 LTR in activated human CD4+ T lymphocytes.

HIV-1 transcription can also be modulated in response to T-cell activation by other cellular transactivation proteins such as NFAT and AP-1. Like NF- κ B, members of the NFAT family of proteins are sequestered in the cytoplasm and transported into the nucleus after an increase in the levels of intracellular calcium.⁷⁵³ Changes in intracellular calcium concentration activate the calcineurin serine/threonine phosphatase and result in the phosphorylation of NFAT, exposure of the NFAT NLS, and NFAT nuclear translocation. Although, it was originally thought that NFAT binds to a site within the NRE region of the HIV-1 LTR, more recent data show that NFAT recognition sequences map to the 3' halves of the two NF- κ B motifs in the promoter-proximal region of the U3 LTR (Fig. 49.21).³⁹⁷ NFAT binds to DNA as dimers when the subclass of NF- κ B recognition sites found in HIV-1 LTR is present. Because NFAT is known to recruit the co-activator p300 and CBP to cellular promoters, it is likely to mediate nucleosomal disruption in synergy with NF- κ B to positively regulate HIV-1 LTR-directed gene expression.

The rate of HIV-1 viral RNA synthesis can also be stimulated by AP-1, which consists of Jun homodimers or Jun/Fos heterodimers. Depending on the HIV-1 subtype, AP-1 binds to one or two DNA elements located immediately upstream of the two NF- κ B sites in the HIV-1 LTR (Table 49.2). AP-1 has also been shown to cooperate with NF- κ B and activate the viral promoter via the two NF- κ B-binding motifs. AP-1 is activated by the c-Jun N-terminal kinase (JNK) and the extracellular signal-related kinase (ERK).³⁷⁶

The HIV-2 LTR also contains three Sp1 binding sites adjacent to its TATA box, but the organization of its upstream

enhancer region is different from that of HIV-1 (Fig. 49.21, bottom). This portion of the HIV-2 U3 LTR contains only a single functional NF- κ B motif as well as immediately upstream E26 transforming specific (Ets) and peri-ets (pets) binding sites.⁴⁹⁶ The two purine-rich Ets sequences are recognized by a family of proto-oncogene proteins (mainly Elf-1), and the human autoantigen DEK binds to the pets site. Thus, whereas activation of HIV-1 LTR-directed expression after T-cell activation is mediated primarily through the binding of NF- κ B to its two cognate sites, induction of HIV-2 gene expression is stimulated by a different set of cellular transactivators.

In eukaryotic cells the interactions of transcriptional regulatory proteins with their cognate *cis*-acting elements is further modulated by the packaging of DNA into chromatin. This is clearly the case for HIV-1 proviral DNA, which becomes stably integrated into host cell chromosomal DNA during productive viral infections. DNA footprinting and restriction enzyme accessibility studies of integrated viral DNA have in fact revealed the presence of nucleosomes located both upstream and downstream of the HIV-1 promoter (designated nuc-0, nuc-1, and nuc-2, respectively, in Fig. 49.21).¹⁴⁶ Nucleosome positioning defines two open chromatin regions encompassing (a) promoter/enhancer sequences (–250 to +11 [relative to the transcription start site]) and (b) a downstream segment that begins within the 3' portion of U5 and extends into the Gag leader (+150 to +250). This scheme of chromatin organization is independent of the provirus integration site. Transcription factors are thought to bind to their cognate recognition motifs to maintain these open chromatin regions. The nucleosome-free region that is promoter distal to nuc-1 and located downstream of the transcription start site contains recognition sites for three different transcription factors: AP-3-like, DBF-1, and Sp1 (Fig. 49.21). Mutagenesis of these binding motifs effectively abolishes the downstream nucleosome-free zone and markedly inhibits the transcriptional activity of the HIV-1 promoter in the context of both stably integrated LTR constructs and infections mediated by mutagenized cell-free virus.^{201,766} Taken together, these results are consistent with a model in which the positioning of nucleosome nuc-1 immediately downstream of the transcription start site sterically impedes transcription initiation and/or elongation, resulting in the characteristically low basal (uninduced) levels of HIV-1 RNA synthesis. The positioning of nuc1 is thought to reflect the binding of transcriptional regulatory factors to upstream promoter/enhancer motifs (*viz.* Sp1 and NF- κ B sites) and downstream recognition sequences situated in the U5/Gag leader region (AP-3-like, DBF-1, and Sp1), a combination that creates the two nucleosome-free regions. Transcriptional activation of cells containing the integrated HIV-1 LTR with Tat, TNF α , or inhibitors of histone deacetylation specifically results in the rapid remodeling of nucleosome nuc-1 and generates a 500-bp open chromatin region.

HIV-Encoded Regulatory Proteins

Tat

Although the mechanism underlying Tat transactivation of HIV LTR-directed expression was hotly debated for several years, it is now generally agreed upon that Tat increases the steady-state levels of viral RNA several hundredfold by directing the formation of a more processive RNA Pol II transcription complex in virus-infected cells. Tat is an indispensable viral

protein; when the HIV-1 *tat* gene is mutagenized, no detectable progeny virions are produced.^{170,222} HIV-1 Tat is a nuclear protein containing 101 amino acid residues encoded by two exons (Fig. 49.22). A shorter 72-amino acid “one-exon” HIV-1 Tat protein possesses all the transcriptional activating properties of full-length Tat, as measured in tissue culture infections or in LTR-driven reporter gene experiments. The termination codon following the first Tat exon is highly conserved among diverse HIV-1 isolates, suggesting that the “one-exon” and “two-exon” Tat proteins may mediate different functions during productive viral infections *in vivo*.

As previously noted, RNA synthesis in eukaryotic cells is usually modulated by transcription activator proteins, which bind to DNA motifs located *upstream* of their respective promoters and recruit GTFs and the RNA Pol II holoenzyme to the transcription initiation complex. Visna virus, another member of the *Lentivirus* genus, in fact encodes a DNA-binding Tat protein, which binds to AP-1 sites located in its LTR upstream of the transcription start site. In contrast, the targets of all primate lentiviral Tat transactivating proteins are sequences situated *downstream* of the start site for viral RNA synthesis.⁶³⁹ The basis for this unusual property was subsequently elucidated when it

was demonstrated that TAR does not function as a DNA recognition site but as an RNA structural element (see Fig. 49.7).⁵⁰

HIV-1 TAR encompasses the 5′ terminal 59 nt of *all* viral RNAs and folds into a stable stem-loop structure (Fig. 49.22). The minimal TAR element (mapping between bases +19 and +42) contains three critical components: a base-paired stem, a trinucleotide bulge (containing the sequence UCU at positions +23 to +25), and a hexanucleotide G-rich loop.²¹⁵ Interestingly, HIV-2 TAR forms a double stem-loop structure, each arm of which possesses a dinucleotide bulge and the hexanucleotide G-rich loop (Fig. 49.22).²⁰³ Sequences located in both the hexanucleotide loop and the bulge of HIV-1 TAR are required for Tat function. HIV-1 Tat binds to WT or “loop” mutants of TAR but *not* to TAR elements containing alterations affecting the bulge region.^{185,646} Modifications of the invariant “bulge” U₊₂₃ nucleotide and elimination of the base pairs immediately above and below the bulge (Fig. 49.22) significantly reduce the binding of Tat to TAR.⁷⁹² NMR studies have shown that the binding of a Tat peptide to TAR causes the major groove in the RNA duplex to widen, thereby generating multiple points of contact between Arg residues in the binding domain of Tat with critical nucleotides (e.g., U₊₂₃) and several phosphate groups

FIGURE 49.22. Tat and its transactivation response region (TAR) element. Schematic representation of the human immunodeficiency virus 1 (HIV-1) Tat protein (**top**) with the cysteine-rich activation, core, and TAR-binding domains indicated. The stem-bulge-loop configurations of HIV-1 and HIV-2 TAR elements are shown in the **middle**. The production of fully elongated HIV-1 messenger RNA (mRNA) molecules generated in the presence of Tat, compared with short HIV-1 transcripts, prematurely released from the DNA template in the absence of Tat, is depicted at the **bottom**.

comprising the TAR backbone.¹ This distortion of the TAR structure also brings the loop and bulge regions into close proximity, which could facilitate the interactions of the proteins binding to both of these TAR domains (see later).

The functional organization of the HIV-1 Tat protein has been deduced from TAR binding and transcriptional activation experiments using both WT and mutagenized derivatives of the Tat protein. The tripartite Tat activation (or effector) domain encompasses the N-terminal 48 residues, which include (a) a string of highly acidic amino acids (residues 1 to 21); (b) a Cys-rich region (seven invariant, six of which are required for function) between positions 22 and 37; and (c) a hydrophobic core segment (amino acids 38 to 48), which is highly conserved among different HIV isolates (see Fig. 49.22). The activation domain is critical for recruiting an essential cellular co-factor to TAR; mutations affecting this region of the Tat protein drastically reduce or eliminate transactivation activity.⁶⁴⁷ The TAR RNA-binding domain of Tat has been mapped to a Lys/Arg-rich region between residues 48 and 57 (Fig. 49.22); peptides from this Tat segment bind to the TAR bulge region as well as to a few base pairs surrounding the bulge, but with somewhat less affinity and specificity than do purified preparations of the full-length Tat protein.¹⁴⁸

The hallmark of HIV LTR-directed RNA synthesis in the *absence* of Tat is the accumulation of prematurely and randomly terminated transcripts, which are converted to longer RNA species when Tat is expressed (Fig. 49.22, bottom). This Tat-deficient phenotype has been observed after the transient transfection of LTR-driven reporter gene constructs in the absence of Tat and in cells harboring integrated HIV-1 proviruses with mutated Tat genes.^{212,426,755} Because Tat expression markedly stimulated transcriptional elongation in these experimental systems, attention shifted to the possible involvement of the CTD of RNA Pol II, which, as noted earlier, is hyperphosphorylated in highly processive transcription complexes. This line of reasoning was also consistent with the reported inhibition of Tat-stimulated transcription by the adenosine analog DRB, which blocks RNA Pol II-mediated elongation *in vitro* and *in vivo* by inactivating protein kinases.⁸⁰ The demonstrated requirement of the Pol II CTD for Tat-mediated transactivation of viral RNA synthesis also supported such a model.^{581,830}

Reports describing the specific interaction of HIV-2 Tat (or just the effector domain of HIV-1 Tat [residues 1 to 48]) with a cellular kinase linked many of these disparate findings and provided the first mechanistic clues about Tat function.^{316,317} The novel cellular enzymatic activity identified, initially named Tat-associated kinase or TAK, was able to phosphorylate the CTD of RNA Pol II. Contemporaneous studies evaluating Tat-stimulated Pol II processivity in cell-free systems indicated that Tat interacted with components of the TFIIF complex to enhance transcriptional elongation and raised the possibility that TAK might be a TFIIF-associated kinase.^{256,581} However, it was subsequently shown that Tat binds with high affinity to a Pol II CTD kinase complex⁸⁶³ related to the *Drosophila* multicomponent P-TEFb, which is catalytically independent of TFIIF.^{498,590,591}

The Tat-related kinase component in human P-TEFb was subsequently identified as CDK9, a 42-kD CDC2-related kinase. When antibodies were used to deplete this kinase in nuclear extracts, the residual activity for Tat-stimulated RNA chain elongation was reduced nearly 100-fold.^{590,591,863} Although

earlier studies had shown that P-TEFb interacted with the activation domain of HIV-1 Tat, the CDK9 catalytic subunit itself failed to bind to Tat in *in vitro* assays. Equally perplexing was the identification of the P-TEFb kinase activity in nuclear extracts migrating not as the 42-kD CDK9, but as a 110-kD complex.⁸³⁰ This result suggested the existence of a possible cyclin-related partner for CDK9, which might provide substrate specificity. These unresolved issues were clarified with the isolation of the “missing link”—an 87-kD protein from nuclear extracts, which bound to WT HIV-1 Tat but not to a mutant Tat protein containing a nonfunctional activation domain.⁷⁹³ The sequence of a cDNA clone encoding the 87-kD protein revealed the presence of an N-terminal cyclin box that was nearly 40% identical to human cyclin C. The new protein, initially named cyclin T (because it bound to Tat), is encoded by a gene mapping to human chromosome 12. The CDK9 family of kinases is now known to interact with cyclin regulatory subunits, many of which have been cloned and characterized.⁵⁹⁰ Several human cyclins (T1, T2a, T2b, or K) can functionally partner with CDK9, greatly increasing its kinase activity⁵⁹¹; of these, only cyclin T1 is able to directly bind to the HIV-1 Tat activation domain and is a component of P-TEFb.⁷⁹³

The binding of Tat to TAR has traditionally been the centerpiece of models for Tat-mediated transactivation. After the identification of CDK9 and cyclin T1 as cellular co-factors of Tat, attention turned to determining how they interacted with Tat, TAR, and the cellular transcriptional machinery. A large body of work revealed the following information: (a) CDK9/cyclinT1 is present in eukaryotic cells as an assembled heterodimer whose recruitment into the Pol II complex is associated with highly processive transcriptional activity; (b) recombinant cyclin T1 directly binds to the effector domain of WT Tat but not to Tat proteins containing mutations affecting this region, a result consistent with the reported interaction of Tat and purified human P-TEFb in the absence of TAR^{829,863}; (c) the binding of Tat to TAR RNA is markedly enhanced in the presence of cyclin T1,^{59,255,793} in agreement with reports showing that the interaction of Tat with purified P-TEFb greatly increased the affinity of Tat for TAR⁸⁶⁰; and (d) the Tat–cyclin T1 complex will only bind to TAR RNA in which both the loop and bulge are intact, whereas Tat alone requires only the trinucleotide bulge for stable TAR interaction. Taken together, these results suggest that multiple pair-wise interactions stabilize the binding of Tat to TAR: (a) Tat with P-TEFb, (b) Tat with the TAR bulge, (c) cyclin T1 with the TAR loop, and, (d) the TAR bulge/TAR loop with Tat/P-TEFb.

P-TEFb stimulates transcriptional elongation by phosphorylating both positive and negative elongation factors. As noted earlier, the sequential phosphorylation of the heptad repeats within the CTDs of RNA Pol II at serines 5 and 2 augments polymerase processivity. P-TEFb phosphorylation of the negative elongation factors NELF and DSIF abrogates their suppression of transcriptional elongation.²⁴⁰ Nearly half of P-TEFb is sequestered in an inactive form within ribonucleoprotein complexes containing the HEXIM protein and 7SK small nuclear RNA (snRNA).⁸⁶¹ The association of HEXIM with the cyclin T1 component of P-TEFb inhibits the kinase activity of CDK9. The remaining intracellular P-TEFb is active and associated with the Brd4 bromodomain protein, which directs P-TEFb to actively transcribed genes.⁸³¹ Expression of HIV-1 Tat during

the early phase of productive infection results in the dissociation of 7SK snRNA from P-TEFb and the formation of the Tat/P-TEFb complex.⁶⁸⁷ In this regard, the recently reported crystal structure of HIV-1 Tat complexed with human P-TEFb indicates that Tat makes extensive contacts with both the cyclin T1 subunit and the T-loop of CDK9.⁷⁴⁰ Conformational changes in CDK9 induced by its interaction with Tat may explain its reported altered enzymatic activity to phosphorylate Ser-5 of the RNA Pol II CTD.⁸⁵⁹

Tat transactivation of HIV-1 LTR-driven gene expression is quite low in rodent cells but can be greatly augmented in rodent somatic cell hybrids containing human chromosome 12.³⁰² This defect can also be corrected by overexpressing human cyclin T in rodent cells, which results in enhanced Tat transactivation of the HIV-1 LTR to levels measured in human cells.⁷⁹³ Other studies have shown that the murine homolog of human cyclin T is able to bind to HIV-1 Tat, but the resulting Tat/murine cyclin T heterodimer is not efficiently recruited to TAR.^{241,255} Substitution of Tyr-260 in murine cyclin T with the Cys residue found that that position in the human homolog also restores Tat activity in rodent cells.^{59,255} Thus, the extremely weak activity of Tat in rodent cells is not due to a failure to form the Tat/cyclin T heterodimer; rather, the cross-species heterodimer that does form is unable to bind to TAR and deliver P-TEFb to a poorly processive transcription complex.

A model of HIV Tat transactivation is presented in Figure 49.23. Tat interacts, via its activation domain, with the cyclin T1 subunit of cyclin T1/CDK9, a component of the P-TEFb elongation complex present in the nuclei of virus-infected cells. The binding of human P-TEFb to Tat induces a conformational change in Tat that alters its affinity and specificity for binding to TAR RNA. Thus, the principal function of Tat is to recruit the critical P-TEFb elongation factor to a promoter-proximal location where it can hyperphosphorylate the RNA Pol II CTD, thereby stimulating transcriptional processivity. It is worth noting that expression of both CDK9 and cyclin T1 increases after activation of resting PBMCs with phytohemagglutinin (PHA), phorbol myristic acid (PMA) plus ionomycin, anti-CD3 antibody plus IL-2, or antibodies to both anti-CD3 and the CD28 receptor.³¹⁵ Thus, T-cell activation increases steady-state levels of both NF- κ B and the two cellular co-factors of Tat, resulting in high levels of HIV-1 LTR-directed gene activity.

As noted earlier in this section, the TFIIH kinase, which phosphorylates the RNA Pol II CTD, also binds to the Tat activation domain. TFIIH is part of the preinitiation transcription complex that assembles on the promoter and is then lost from the complex during the early elongation phase of RNA synthesis.⁸⁴⁴ In contrast, P-TEFb is not a component of the preinitiation complex but functions after promoter clearance. Because P-TEFb preferentially phosphorylates a partially

FIGURE 49.23. Tat-promoted phosphorylation of the C-terminal domain (CTD) of RNA polymerase II (Pol II) results in processive synthesis of human immunodeficiency virus 1 (HIV-1) messenger RNA (mRNA). **A:** In the absence of Tat binding to transactivation response region (TAR), the processivity of the RNA Pol II complex is impaired. **B:** When the activation domain (*) of Tat interacts with the cyclin T (cyc T)–CDK9 complex, the conformation of Tat changes and its affinity and specificity for TAR RNA increase. **C:** By recruiting cyc T and CDK9 (the Tat-associated kinase [TAK] complex) to a promoter-proximal location, Tat mediates the hyperphosphorylation of the CTD and promoter clearance (elongation) of the transcriptional complex.

phosphorylated CTD, it has been suggested that CAK and P-TEFb act sequentially during HIV-1 RNA synthesis.⁸³² By interacting with the two kinases, Tat may be able to stimulate both phases of the elongation reaction.

In addition to initiating productive virus infections, HIV-1 is also able to establish latent infections in resting memory CD4⁺ T cells, both in untreated individuals and in patients receiving HAART.^{136,218} Latently infected lymphocytes carry a replication competent integrated provirus, which is transcriptionally silent as long as the cells remain quiescent. As a consequence, these infected T cells are invisible to the immune system. The size of this *in vivo* reservoir is quite small (approximately 10⁵ to 10⁶ cells), has an estimated half-life of 44 months, and is the primary source of viremia following cessation of HAART.⁶⁹⁹ Latently infected memory CD4⁺ T cells represent the principal barrier to HIV-1 eradication. There has been debate as to whether the very low level of viremia (less than 50 copies of viral RNA/mL of plasma) detected in patients on suppressive antiretroviral therapy^{580,812} is the result of ongoing virus replication, perhaps in tissues not efficiently accessed by the antiretrovirals, or the release of small numbers of virus particles from the latent reservoir. Evidence against the hypothesis of ongoing virus replication includes the observation that (a) treatment intensification—adding the integrase inhibitor raltegravir or other potent antiretroviral drugs on top of the suppressive HAART regimen—does not result in further reductions in viral loads^{186,513} and (b) the acquisition of drug resistance mutations is typically not detected during fully suppressive antiretroviral therapy, as would be expected if even low-level virus replication were occurring.^{186,313} However, the source of low-level viremia in patients on HAART remains to be fully defined.

The mechanisms responsible for the establishment and maintenance of latently infected CD4⁺ T cells have only been partially elucidated. It is not presently known whether they arise by the reversion of activated infected cells to a quiescent central memory T-lymphocyte phenotype^{75,495} or are the product of a direct infection of resting CD4⁺ T cells.⁹⁸ Consistent with previous studies reporting that HIV-1 preferentially integrates into active cellular genes,^{442,675} proviruses in resting CD4⁺ T cells recovered from patients on HAART have been found to be integrated into the introns of transcriptionally active cellular genes.^{291,821} This result would support an epigenetic silencing mechanism for mediating the establishment of viral latency.

Several *in vitro* cell systems have been used to investigate how postintegration latency is maintained. The earliest studies, employing cultured human T-cell lines surviving HIV-1 infections, identified the existence of two nucleosomes (nuc 0 and nuc 1 [see Fig. 49.21]) surrounding the viral promoter, which completely blocked transcription initiation. Incubation of these cells with inhibitors of histone deacetylases (HDACs) resulted in chromatin remodeling.⁷⁶⁷ Later work, using chromatin immunoprecipitation assays, reported that hyperacetylation of histone H4 at nuc 1, following HDAC treatment, correlated with activation of HIV-1 LTR-directed transcription.³⁰⁹ The subsequent development and use of clonal cell lines, derived from infected Jurkat cells, revealed that suppressed HIV-1 transcription could arise by multiple mechanisms including repressed chromatin, transcriptional interference, and the absence of transcription elongation factors or the virus-encoded Tat protein.^{367,435,794,804,805} More recently, several groups have developed primary resting human

CD4⁺ T-cell systems exhibiting HIV latency by co-cultivation, manipulation of interleukin levels, or the use of the antiapoptotic protein Bcl-2.^{381,495,652,828} The production of sufficient quantities of viable, latently infected cells remains problematic with these primary CD4⁺ T-cell systems. Recent studies have described an *in vivo* model for HIV-1 latency using the humanized bone marrow–liver–thymus mouse system.^{182,497}

Complementary biochemical and genetic analyses of tissue culture models of HIV-1 latency have shown that the recruited HDACs and histone acetyl transferases (HATs) do not directly interact with the proviral LTR. Rather, transcription regulatory proteins, binding to *cis*-acting LTR elements, recruit both positive and negative factors, which modulate chromatin structure. Some of these are indicated in Figure 49.21 and include NF- κ B, Sp1, leader-binding protein-1 (LBP-1), AP-1, NFAT, and the HIV-1–encoded Tat protein, all of which can recruit chromatin-modifying factors. For example, in latently infected cells, NF- κ B p50/p50 homodimers, lacking the transactivation domain present in the NF- κ B p50/p65 heterodimer, bind to the HIV-1 LTR and recruit HDAC-1 and HDAC-3 to the viral promoter.^{321,804} This leads to histone deacetylation and gene silencing. In contrast, in activated cells, NF- κ B p50/p65 heterodimers are rapidly imported into the nucleus, displace the NF- κ B p50/p50 homodimers, and recruit the HAT p300, thereby mediating local histone acetylation and optimizing Tat function.^{392,472} NFAT, AP-1, and Tat have all been shown to recruit activating factors to the HIV-1 LTR, while LBP-1 attracts chromatin-modifying repressors.^{43,103,445,637}

Taken together, these findings support a model of latently infected resting memory CD4⁺ T cells in which HIV-1 transcription is potently suppressed, Tat is absent, and repressed chromatin prevents the clearance of the preinitiation complex and RNA Pol II processivity.⁷⁵⁹ Under these conditions, nuc 1 is constitutively deacetylated by HDACs, NF- κ B and NFAT are sequestered in the cytoplasm, and the Tat co-factor, P-TEFb, is present in an inactive form within a large RNA-binding protein complex that includes 7SK RNA and HEXIM1. Following activation, NF- κ B p50/p65 heterodimers, NFAT, AP-1, and other positive factors are imported into the nucleus, bind to their cognate sites in the HIV-1 LTR, and recruit HATs or P-TEFb (via the Tat/TAR complex present at the 5′ terminus of all viral RNA transcripts) to the promoter.

REV

Like other primary RNA transcripts synthesized in eukaryotic cells, HIV pre-mRNAs undergo a series of modifications (capping, 3′ end cleavage, polyadenylation, and splicing) prior to their export to the cytoplasm. Retroviruses utilize the cellular posttranscriptional processing machinery to carry out these functions. With few exceptions, introns present in nascent cellular mRNAs must be removed prior to their export from the nucleus, presumably to prevent their translation into nonfunctional proteins. This requirement poses an obvious problem for retroviruses such as HIV, which must export a variety of intron-containing mRNAs into the cytoplasm (e.g., the unspliced 9.2-kb primary transcript for encapsidation into progeny virions and production of Gag and Pol proteins, as well as several other partially spliced mRNAs such as those encoding Env, Vif, and Vpr proteins). In part, retroviruses have solved the requirement for the removal of all intronic sequences from pre-mRNAs prior to nuclear export by incorporating suboptimal 3′ splice acceptors into

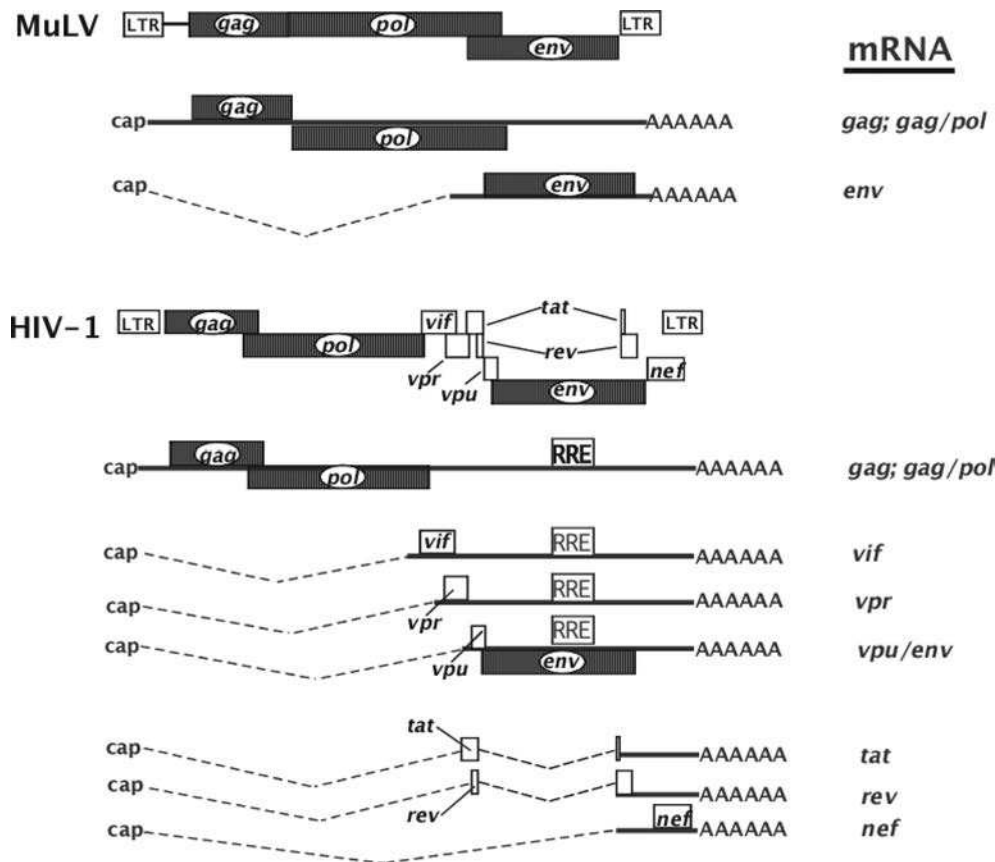

FIGURE 49.24. Retrovirus splicing patterns. In contrast to murine leukemia virus (MLV), which generates only two discrete messenger RNA (mRNA) species (the unspliced *gag/pol* and the singly spliced *env*), human immunodeficiency virus 1 (HIV-1) produces several alternatively spliced mRNAs, ranging from the unspliced *gag/pol* to the multiply spliced *tat*, *rev*, and *nef* RNA transcripts. The genomic organization of the proviral DNA, the location of protein coding sequences, and the position of the Rev-responsive element (RRE) in intron-containing mRNAs encoding viral structural proteins are indicated. The dashed lines connect the major splice donor to a downstream splice acceptor; alternative forms of *tat*, *rev*, *vpu/env*, and *nef* mRNA, some of which contain short upstream noncoding exons, are not shown.

their genomes. These acceptors are functionally impaired due to short or interrupted polypyrimidine tracts, noncanonical branch points, and the presence of *cis*-acting inhibitory sequences, which dampen splice site usage. For example, the presence of purines within the polypyrimidine tracts associated with some HIV-1 3' splice sites impairs splicing by reducing the affinity for the essential cellular splicing factor U2AF.^{268,717}

All retroviruses must splice their primary RNA transcripts to generate *env* mRNAs, eliminating upstream *gag* and *pol* sequences in the process. For simple retroviruses such as the ALVs and MLVs, this is the only splicing reaction that the viral pre-mRNA undergoes (Fig. 49.24, top). In contrast, the splicing of HIV RNA is far more complex because of the presence of both constitutive and alternatively used splice-donor and splice-acceptor motifs scattered through its genomic RNA. Three general classes of HIV-1 mRNAs have been identified in productively infected cells: (a) unspliced genomic RNA, which serves as the mRNA for synthesis of Gag and Pol proteins; (b) partially spliced RNAs, approximately 4.3 to 5.5 kb in size, which are translated into Vif, Vpr, Vpu, and Env proteins; and (c) multiply or completely spliced viral mRNAs, ranging from 1.7 to 2.0 kb in size, which encode the Tat, Rev, and Nef pro-

teins (Fig. 49.24, bottom). The first two classes of viral mRNA contain several spliceable introns yet are efficiently exported from the nucleus into the cytoplasm.

Analyses of viral mRNAs by RT-PCR have revealed the existence of more than 40 different HIV-1 transcripts in virus-producing cells.^{619,685} These mRNAs are generated as a consequence of alternative selection of the four splice donors (sd) and the eight splice acceptors (sa) embedded in the viral genome (some of which are shown at the top of Fig. 49.25). The frequency at which particular 5' and 3' splice sites are used is dependent on the relative strength of each site and the presence of adjacent *cis*-acting RNA elements. These elements include exonic and intronic splicing silencers and exonic splicing enhancers. These enhancer and silencing sequences modulate alternative splicing of the HIV-1 primary RNA transcript by binding to SR proteins and heterogeneous ribonucleoprotein particles (hnRNPs) (reviewed in⁷²²). Variable usage of HIV 5' and 3' splice sites gives rise to several sets of distinct, closely related RNAs that serve as alternative templates for translation into the same protein. For example, 12 different *rev*, 5 different *nef*, 8 different *tat*, and 16 different *env* mRNAs have been identified.⁶¹⁹ This diversity of HIV-1 mRNA is due, in part, to

FIGURE 49.25. Structure and relative abundance of differentially spliced human immunodeficiency virus 1 (HIV-1) *env* messenger RNAs (mRNAs). For each RNA species, the dark bars and associated 3' arrows represent exons included in the spliced transcript as determined by semiquantitative polymerase chain reaction (PCR) analysis. The relative proportion of each mRNA is indicated at the right.

the variable inclusion of two upstream 50- and 74-nt noncoding exons (generated from sa2a/sd2 and sa3a/sd3, respectively; Fig. 49.25) in many of the spliced RNA species. The functional significance of multiply spliced mRNAs encoding the same viral protein, their relative abundance, and the hierarchy of HIV-1 splice site usage are not presently understood.

Complex retroviruses, such as HIV, have dealt with the restriction to the nuclear export of unspliced and incompletely spliced transcripts by incorporating a novel reading frame, encoding the Rev (Regulator of expression of viral proteins) protein, into their genomes. In the absence of Rev, the unspliced *gag/pol* and the partially spliced *vif*, *vpr*, and *vpu/env* mRNAs fail to accumulate in the cytoplasm, thereby rendering the Rev-mutant viruses replication incompetent.^{213,290}

HIV-1 Rev is a 19-kD, predominantly nucleolar phosphoprotein containing 116 amino acid residues (Fig. 49.26). Like Tat, Rev is encoded by two exons and contains two functional regions: (a) an Arg-rich domain that mediates RNA binding and nuclear localization, flanked by sequences that facilitate Rev multimerization, and (b) a hydrophobic segment, located between residues 73 and 84, that contains several Leu residues within an activation domain, which also promotes nuclear export.^{33,482} Mutation of any one of three critical leucines (residues 78, 81, or 83) within this domain eliminates Rev activity. Unlike *tat*, both *rev* exons are required for virus replication.⁶⁵⁰ The HIV Rev protein regulates the expression and usage of viral transcripts by binding to a *cis*-acting target, the RRE, present in all unspliced and partially spliced viral mRNAs (see Figs. 49.7 and 49.26, bottom). The RRE, located in a 250-nt segment spanning the junction between gp120 and gp41 coding sequences of the *env* gene, is a complex RNA structure containing multiple stem-loops branching from a large central bubble^{213,483,640} (Fig. 49.26, bottom). The RRE must be present *within* a Rev-responsive transcript and in the *sense* orientation to confer Rev responsiveness. Nuclease protection, chemical modification, and mutagenesis studies indicate that

Rev specifically interacts with a 60+ nt portion of the RRE, designated stem-loop II (Fig. 49.26).^{171,324,484} This region of the RRE binds to Rev even when isolated from the complete RRE structure and mediates Rev responsiveness in functional assays.³³⁴ The determinants for high-affinity binding of Rev to RRE reside in the central purine-rich “bubble” of stem-loop II; this bubble contains unusual G:G and G:A base pairs that distort the duplex RNA structure and widen the major groove to accommodate the Rev protein.^{33,325,484} NMR analyses have shown that an α -helical, Arg-rich, 17-residue peptide from the RNA-binding domain of Rev burrows deep into the major groove of a stem-loop II oligonucleotide, stabilizing the non-Watson-Crick base pairs through specific interactions involving the Arg side chains.³⁵ The functionally complete RRE is approximately 350 nt in size, and an individual element may accommodate at least six Rev molecules.^{165,166,489}

It was initially believed that a dimer of Rev makes the initial contact with the RRE. A more recent study indicates that Rev binds to the stem-loop IIB region of RRE as a monomer.⁶⁰⁴ A crystal structure of truncated (N-terminal 70 aa) Rev bound to the RRE revealed that monomeric Rev folds into a helix-loop-helix structure, creating a hydrophobic core.¹⁶⁷ This core region becomes a dimerization interface for the cooperative binding of a second Rev monomer, which also interacts with a contiguous region of the RRE, thereby generating a “V”-shaped dimer structure. Further oligomerization of similarly organized dimers cooperatively assembles into a tightly bound hexameric Rev-RRE RNA ribonucleoprotein (RNP) primed for nuclear export.

Mutations affecting either the RNA-binding or the Leu-rich activation domains of the Rev protein result in loss of function. For example, activation domain mutants are able to bind to the RRE but are functionally inactive. They interfere with the transactivation mediated by WT Rev, exerting a *trans*-dominant effect in assays for Rev function.⁴⁸² Rev is also able to continuously shuttle between the nucleus and cytoplasm.⁵²⁰

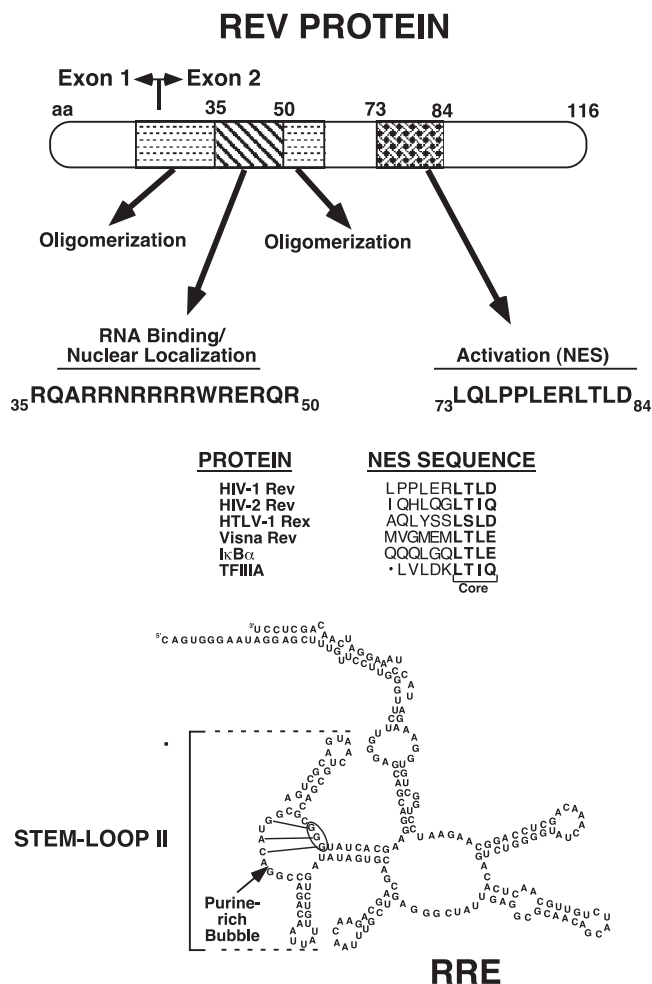

FIGURE 49.26. Rev and its response element, the RRE. A schematic representation of the human immunodeficiency virus 1 (HIV-1) Rev protein with its RNA-binding, activation, and oligomerization domains is shown at the **top**. The amino acid sequence of the leucine-rich nuclear export signal (NES) present in retroviral Rev/Rex proteins and two cellular proteins is also shown. The core tetramer motif, LxLy, where y is usually a charged residue and x is highly variable, is indicated. The structure of the RRE is presented at the **bottom** with the high-affinity target of HIV-1 Rev (stem-loop II) shown. The “bulged” G residues in stem-loop II able to form noncanonical purine-purine base pairs are circled.

Mutations affecting the Rev activation domain abolish shuttling and restrict Rev to the nucleus. Multimerization-defective Rev mutants can still bind to the high-affinity RRE site but are unable to form oligomeric complexes.⁴⁷⁶

As noted earlier, the HIV-1 genome contains multiple sequence motifs, located in the *gag*, *pol*, and *env* genes (and designated INS in Fig. 49.7), which contribute to a requirement for Rev. These *cis*-acting, AU-rich INS elements markedly impaired the expression of fused reporter genes by impeding RNA transport to the cytoplasm and/or decreasing RNA stability.^{480,640} It is quite likely that cellular proteins bind to these inhibitory sequences, contributing to the nuclear retention and the intrinsic instability of intron-containing viral RNAs. Rev is able to reverse these effects, provided that an RRE is present in such transcripts.

Although the total amount of viral RNA in cells infected with WT or Rev-deficient HIV mutants is quite similar, *gag-pol*, *env*, *vif*, and *vpr* mRNAs are either absent or markedly underrepresented in the cytoplasm of cells infected with Rev mutants compared to the levels of multiply spliced *tat*, *rev*, and *nef* transcripts in this compartment.^{213,483} Although several models were initially proposed to explain Rev function, careful analyses of HIV-1 RNA expression patterns indicated that the ratios of unspliced (or partially spliced) to completely spliced viral transcripts in the nucleus did *not* change in the presence or absence of Rev.^{213,483} Rather, the Rev⁻ phenotype was characterized by a superabundance of the 1.7- to 2.0-kb completely spliced RNAs in the cytoplasm and by greatly reduced or no detectable cytoplasmic RRE-containing unspliced or partially spliced mRNAs. Because splicing of viral RNA in the nucleus was not affected by the absence of Rev, attention shifted to the role that Rev might have on HIV-1 RNA transport.

The first unambiguous demonstration that Rev could promote the nuclear export of intron-containing viral RNA came from experiments in which purified Rev protein and RRE-containing RNA molecules were microinjected into cell nuclei.^{219,799} These studies showed that the RRE-containing unspliced RNA substrates were transported from the nucleus into the cytoplasm only in the presence of Rev. Interestingly, the excised exon (containing the RRE), derived from those transcripts that did undergo splicing, was also detected in the cytoplasm, indicating that Rev was able to mediate nuclear export *without* inhibiting RNA splicing.²²⁰ Other microinjection studies revealed that the Leu-rich Rev activation domain was indeed a nuclear export signal (NES) because, when fused to bovine serum albumin (BSA), it promoted the transport of NES/BSA molecules into the cytoplasm.^{219,799} In contrast, NES/BSA fusion proteins containing a mutated, nonfunctional Leu-rich Rev domain remained in the nucleus. The nuclear export mediated by the Rev NES was also shown to be energy dependent and was blocked by high concentrations of NES/BSA, a result that implied that the amounts of intracellular nucleus-to-cytoplasm transporting proteins were limiting. Surprisingly, the nuclear export of 5S ribosomal RNA (rRNA) and spliceosomal U (sn)RNAs, but not RNA Pol II-derived cellular mRNAs, was also inhibited when high concentrations of NES/BSA conjugates were microinjected. In this regard, a growing list of viral and cellular proteins involved in RNA metabolism and signal transduction have been shown to contain a Rev-like, Leu-rich NESs (Fig. 49.26, middle), which mediates the transport of a variety of substrates from the nucleus to the cytoplasm.^{351,505} Taken together, these results are consistent with a model in which the Rev effector domain functions as an NES, directing RRE-containing viral RNAs to the cytoplasm via a pathway used by some cellular mRNAs.

The bidirectional passage of proteins between the nucleus and cytoplasm occurs through the nuclear pore complex (NPC) and depends on the presence of NLSs and NESs (reviewed in^{283,719}). The NPC is an extremely large (greater than 100-MDa) gated structure composed of 50 to 100 different proteins, called nucleoporins. One class of nucleoporins, thought to directly participate in nuclear-cytoplasmic transport, contains Phe-Gly (FG) repeat domains and is located primarily at the periphery of the NPC. Proteins destined to be imported into the nucleus (e.g., bearing a typical basic-type NLS) initially associate with a member of a growing family of transport

“receptors” in the cytoplasm. The first receptor of this type discovered, importin- β , shares structural features and interacting partners with other family members and is considered to be the prototypical transporter. Proteins bearing the basic-type NLS usually begin the nuclear import process by binding to a related transport protein, importin- α . Importin- α serves as a bridge, linking the NLS-containing substrate to importin- β . However, in contrast to most other proteins that carry a classic NLS, Rev appears to bind directly to importin- β . Furthermore, this heterodimeric complex is transported to the NPC, where the importin- β subunit successively binds to and dissociates from the resident nucleoporins, translocating the Rev substrate through the pore and into the nucleoplasm. It is now known that the reverse process, nuclear export, uses transport receptors that are also members of the importin- β family. The best characterized of these is named Crm1 (for chromosome region maintenance 1), or exportin 1. Studies of HIV-1 Rev and related viral and cellular proteins bearing Leu-rich NES motifs (Fig. 49.26) have led to the discovery and established the functions of many proteins involved in nuclear export.

The small guanosine triphosphatase (GTPase) molecule, Ran,⁶² provides both the energy and directionality cues for nuclear import and export. Intracellularly, Ran cycles between two forms, Ran guanosine triphosphate (RanGTP) and Ran guanosine diphosphate (RanGDP), which are concentrated primarily in the nucleus and cytoplasm, respectively.³⁵² The specificity of Ran activity in nuclear transport is regulated by the nature of the bound nucleotide. Several cellular proteins are able to modulate the nucleotide-bound state of Ran and therefore contribute to the asymmetric distribution of the two Ran forms.⁶² One of these, the chromatin-associated regulator of chromosomal condensation 1 (RCC1), stimulates the replacement of GDP with GTP when Ran is in the nucleus. Conversely, two other factors, Ran GTPase activating protein 1 (Ran GAP1) and Ran binding protein 1 (Ran BP1), both augment Ran activity in the cytoplasm by promoting the hydrolysis of the Ran-associated GTP. The net effect of these interactions is the maintenance of the observed RanGTP/RanGDP intracellular gradient required for nuclear import and export functions.

The complete Rev nuclear transport cycle and its critical interacting partners are shown in Figure 49.27. During the early, postintegration phase of the virus life cycle, the HIV-1 mRNAs transported to the cytoplasm consist almost entirely of intronless, multiply spliced transcripts encoding the Tat, Rev, and Nef proteins. As noted earlier, Rev uses its NLS to bind directly to importin- β in the cytoplasm and is translocated through the nuclear pore as a Rev/importin- β heterodimer. When the complex reaches the nucleus, the binding of RanGTP triggers the Rev/importin- β heterodimer to dissociate and release the Rev subunit. In the nucleoplasm, Rev initiates its role as a nuclear exporter by binding to the high-affinity site on stem-loop II of RRE-containing HIV-1 pre-mRNAs and then multimerizes via cooperative protein–protein and protein–RNA interactions over the entire length of the RRE. When Rev oligomerizes on the RRE, its NES elements become aligned on the outside of an enlarging protein–RNA complex. Multimerized Rev/RRE then forms a functional complex with CRM1 in the presence of Ran in its GTP-bound form. The formation of this RNP is (a) sensitive to Rev NES mutations and (b) dissociated when RanGTP is hydrolyzed to its GDP-bound state.²⁶ The most

likely scenario linking all available data is that the entry of RanGTP into a pre-existing Rev/RRE/CRM1 RNP converts it into a functional export complex. Once the complex is formed, it is transported to the NPC, where the CRM1 subunit interacts with nucleoporins,²²⁴ and is then translocated into the cytoplasm. There, in the presence of Ran GAP1 and Ran BP1, the RanGTP component of the export complex is converted to the RanGDP form and the RNP disassembles.^{273,561} Rev is released along with its unspliced and partially spliced HIV-1 RNA “cargo,” allowing the latter to be incorporated into progeny virions or translated into viral proteins. Rev therefore enables lentiviral intron-containing RNAs to elude the cellular splicing machinery and be transported to the cytoplasm via an export pathway not used by most cellular mRNAs.

Virus Assembly and Release: The Gag Proteins

The Gag proteins of HIV, like those of other retroviruses, are necessary and sufficient for the formation of noninfectious, virus-like particles (VLPs). Retroviral Gag proteins are generally synthesized as polyprotein precursors, Pr55^{Gag} in the case of HIV-1. As noted previously, the mRNA for Pr55^{Gag} is the unspliced 9.2-kb transcript that requires Rev for its expression in the cytoplasm. The HIV Pr55^{Gag} precursor is targeted to the membrane rapidly after its synthesis. At the membrane, particles of sufficient size and density to be visible by EM are assembled. The formation of noninfectious VLPs does not require the participation of viral genomic RNA (although the presence of nucleic acid appears to be essential), *pol*-encoded enzymes, or Env glycoproteins. However, the production of *infectious* virions requires the encapsidation of the viral RNA genome and the incorporation of the Env glycoproteins and the Gag-Pol polyprotein precursor Pr160^{Gag-Pol}. Retroviral Gag proteins perform several major functions during virus assembly, including (a) forming the structural framework of the virion, (b) encapsidating the viral genome, (c) targeting the nascent particle for export from the cell, and (d) acquiring a lipid bilayer and associated Env glycoproteins during particle release (for review see⁸⁴). These processes require that Gag proteins participate in protein–protein, protein–RNA, and protein–lipid interactions. As described later, Gag proteins also play critical roles in the early stages of the virus replication cycle.

In the immature VLP, Gag monomers are aligned and packed radially, with the MA domain in association with the inner leaflet of the lipid bilayer and the NC domain bound to genomic viral RNA facing the center of the virion (Fig. 49.28). Gag–Gag contacts are primarily mediated through the CTD of CA and SP1. Tomographic analyses have demonstrated that in immature VLPs Gag forms a hexameric lattice^{85,173,815} (see later). The ability of the Gag lattice to curve into a sphere is afforded by a large gap in the lattice. The CA NTD is arranged in a ring around a central hole in each hexamer; the CA CTD is positioned just below the NTD and links the hexamers together to form the lattice.⁸⁵ The C-terminus of the CA CTD and adjoining SP1 are proposed to be helical,⁵³⁷ and cryoelectron tomography results suggest that the CA–SP1 junction region forms a bundle of helices that connects CA to NC.⁸¹⁵ Estimates of Gag content per virion have ranged from several thousand to ~5,000 molecules. Studies showing that the Gag lattice is continuous but contains a large gap are consistent with the lower end of this range (~2,500 molecules of Gag/particle).¹⁰⁵

FIGURE 49.27. Rev nuclear export pathway. Intronless multiply spliced human immunodeficiency virus 1 (HIV-1) messenger RNAs (mRNAs) (*tat*, *rev*, and *nef*) use a Rev-independent pathway to exit the nucleus (1). Using its nuclear localization signal (NLS), newly synthesized Rev protein binds to importin β (2) and the resulting heterodimer (3) is translocated through the nuclear pore. In the nucleus, Rev/importin β dissociation is mediated by Ran(GTP) (4) and the free Rev protein (5) binds to Rev-responsive element (RRE)-containing viral pre-mRNA (6). The Rev-RRE RNA complex is converted to a functional export structure following the addition of CRM1 and Ran(GTP) (7) and is transported through the nuclear pore (8). In the cytoplasm, RanBP1/RanGAP mediate the conversion of Ran(GTP) in the export complex to Ran(GDP) (9), which then disassembles. After the release of Rev from intron-containing HIV-1 transcripts (10), the full-length viral RNA may be encapsidated into progeny virions or, as is the case for the partially spliced mRNA, may be translated into viral proteins (11).

When the *pol* ORF is expressed, the viral PR cleaves Pr55^{Gag} during or shortly after budding and release from the cell to generate the mature Gag proteins MA, CA, NC, and p6. Two spacer peptides are also cleaved from the Gag precursor: SP1 (originally called p2), located between CA and NC, and SP2 (originally called p1), situated between NC and p6 (Fig. 49.29A). Processing of the Gag and Gag-Pol precursor proteins by PR results in a major structural and morphologic rearrangement, referred to as maturation, during which the core condenses into the cone-shaped structure characteristic of the mature HIV particle (see section on Virus Maturation). Disruption of this maturation process abolishes virus infectivity. In the mature virion, MA is localized immediately inside the lipid bilayer of the viral envelope, CA forms the cone-shaped core structure in the center of the particle, and NC is present in the core in a ribonucleoprotein complex with the viral RNA genome (see Fig. 49.28). Detailed NMR and x-ray

crystallographic data have provided significant insights into the structure-function relationship of HIV-1 MA, CA, and NC.

Matrix (MA): Membrane Binding and Gag Targeting

The MA domain of Pr55^{Gag} (Fig. 49.29B) performs several essential functions during the viral life cycle. After Gag synthesis, MA directs Pr55^{Gag} to the membrane via a multipartite membrane-binding signal. The affinity of the MA domain for the membrane is provided in part by a myristic acid moiety covalently attached to the N-terminal Gly of MA after removal of the initiator Met by N-myristyl transferase. Mutation of the Gly myristate acceptor blocks binding of Gag to the membrane and abolishes virus assembly in most systems. Sequences in MA downstream of the myristate also contribute to membrane binding. NMR and x-ray crystallographic analyses of HIV-1 MA (as well as the MA protein of a number of other retroviruses) demonstrate that a highly basic patch of amino acids

Schematic representation of immature (C) and mature (D) HIV-1 particles, with labels indicating the gp120/gp41 glycoprotein spike, the lipid bilayer, and the viral RNA. In C, the major domains in Gag (matrix [MA], capsid [CA], nucleocapsid [NC], and p6) and Gag-Pol (protease [PR], reverse transcriptase [RT], and integrase [IN]) are labeled. In D, locations of mature Gag and Pol products are indicated. (Modified from Balasubramaniam M, Freed EO. New insights into HIV assembly and trafficking. *Physiology [Bethesda]* 2011;26:236–251.)

clusters on the face of MA predicted to juxtapose the plasma membrane (Fig. 49.30).^{318,502} It has been proposed that these basic residues interact with the negatively charged acidic phospholipids on the inner leaflet of the lipid bilayer, thereby stabilizing membrane interactions.^{314,502,862} As discussed in more detail later, mutations affecting these basic residues can disrupt the targeting of Gag to the plasma membrane.^{238,842,862}

Structural analysis of myristylated MA has indicated that the myristate moiety is in equilibrium between an exposed and a sequestered conformation.⁷⁴⁶ Myristate exposure appears to be triggered both by Gag multimerization⁷⁴⁶ and by binding of MA to the phospholipid phosphatidylinositol-(4,5)-bisphosphate (PI[4,5]P₂).⁶⁴⁹ In the exposed conformation the myristate is able to insert into the lipid bilayer of the plasma membrane, indicating that both Gag multimerization and PI(4,5)P₂ binding promote Gag–membrane association.

A large body of data indicates that the assembly of electron-density budding structures takes place predominantly at the plasma membrane. Early EM observations demonstrated that in MDMs assembly and budding take place in an internal compartment⁵⁷⁶ that was initially thought to be of late endosomal origin. Subsequent studies, however, showed that these structures are connected to the plasma membrane by a complex network of thin channels^{45,180,798} and thus represent plasma membrane invaginations rather than late endosomes. Real-time imaging of HIV-1 assembly in living MDMs

revealed that virus accumulating in this internal compartment rapidly translocates to the cell–cell junction (the VS discussed earlier) that forms between infected MDMs and uninfected T cells.²⁷⁷ Thus, assembly of HIV-1 particles internally and their movement to the MDM–T-cell VS provide a mechanism for immune evasion coupled with efficient cell–cell transfer.

Early studies indicated that MA contains sequences that regulate the site of virus assembly. Deletion of a large portion of MA redirects HIV-1 assembly to the endoplasmic reticulum,²⁰⁸ whereas single and double amino acid changes between MA residues 84 and 88 and in the highly basic domain of MA (Fig. 49.29B)^{238,572} cause virus assembly to be redirected to multivesicular bodies (MVBs).⁵⁷² Thus, MA contains sequences that not only regulate membrane binding but also determine the specificity of membrane targeting.

Although the cellular determinants that regulate the site of HIV-1 assembly remain to be fully defined, it is clear that PI(4,5)P₂ plays an important role in directing Gag to the plasma membrane. Depleting PI(4,5)P₂ from the plasma membrane leads to the retargeting of HIV-1 assembly to MVBs and severely disrupts virus particle production.⁵⁷¹ As mentioned earlier, structural data indicate that PI(4,5)P₂ binds directly to MA^{649,696} and induces the exposure of the N-terminal myristate.⁶⁴⁹ PI(4,5)P₂ also promotes the binding of Gag to liposomes.¹³³ Some of the basic residues in MA that function in targeting Gag to the plasma membrane^{572,574} appear to

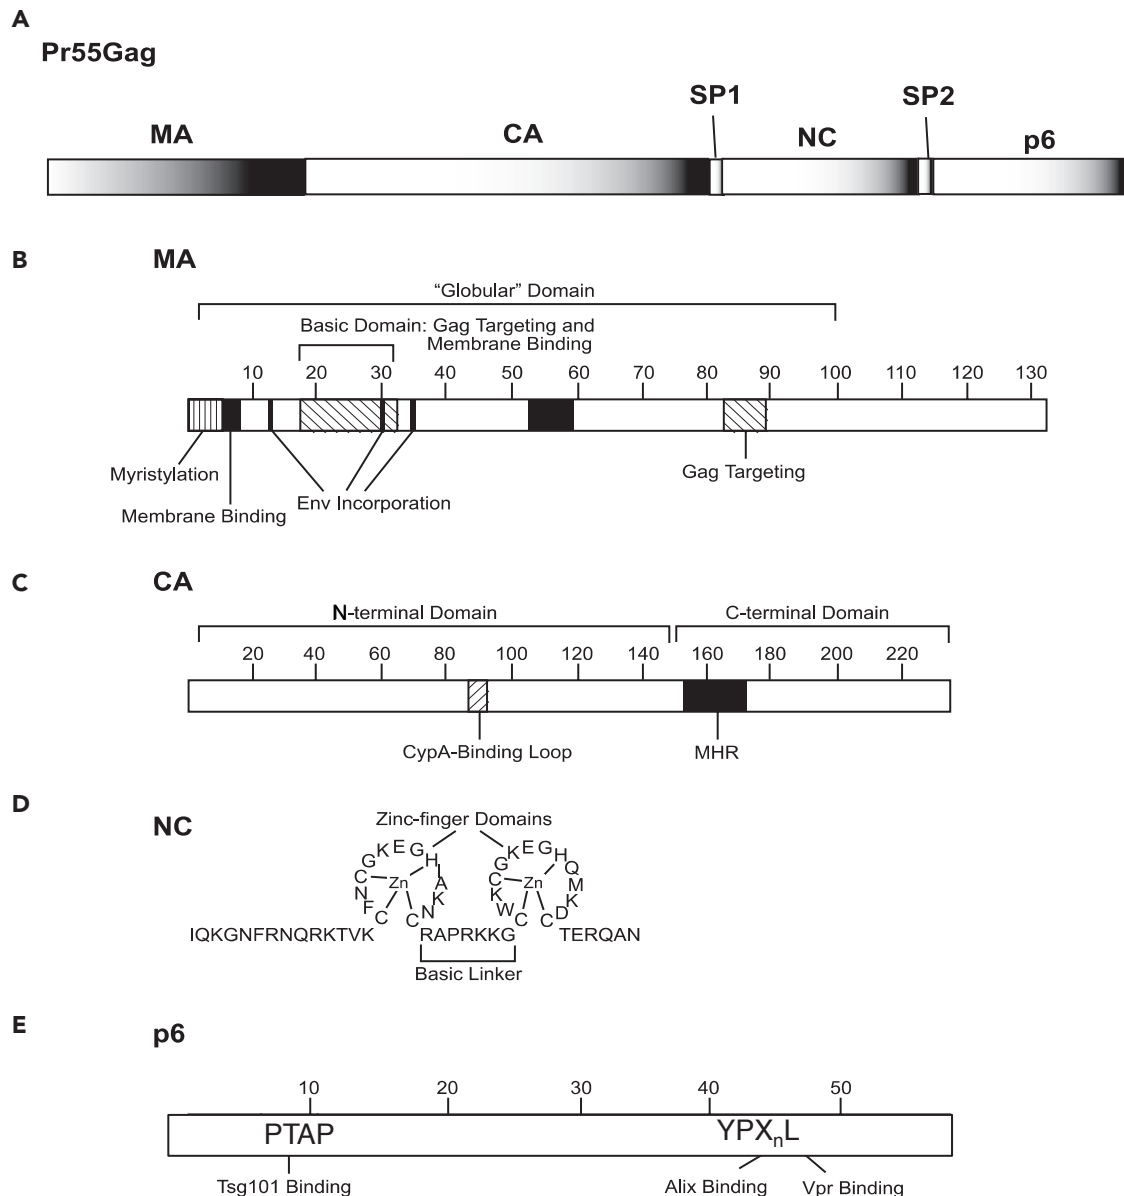

FIGURE 49.29. Linear organization of the major human immunodeficiency virus 1 (HIV-1) Gag proteins. **A:** The Gag precursor, Pr55^{Gag}, with the positions of the matrix (MA), capsid (CA), nucleocapsid (NC), and p6 domains indicated; the spacer peptides, SP1 and SP2, are also shown. **B:** MA. **C:** CA. **D:** NC. **E:** p6. Amino acid positions are indicated, as are major functional domains (details in the text). (Adapted from Freed EO. HIV-1 Gag proteins: diverse functions in the virus life cycle. *Virology* 1998;251:1–15.)

be directly involved in PI(4,5)P₂ binding^{133,696}; mutation of these basic residues thus recapitulates the effect of PI(4,5)P₂ depletion. Interestingly, PI(4,5)P₂ also regulates the membrane binding of several other retroviral Gag proteins, for example, HIV-2⁶⁴⁸ and MLV.²⁸⁹ Although the NC domain of Gag is the primary determinant for Gag–RNA interaction, MA also binds RNA, and this RNA binding reportedly inhibits MA association with PI(4,5)P₂-deficient but not PI(4,5)P₂-containing membranes. This mode of RNA regulation likely contributes to the selectivity of Gag for PI(4,5)P₂-enriched (i.e., plasma) membranes over internal membranes that lack PI(4,5)P₂.^{12,134}

In addition to the phospholipid PI(4,5)P₂, a growing number of host cell proteins have been implicated in HIV-1 assembly and Gag trafficking.²⁹ These include a number of pro-

teins that function in cellular membrane and protein trafficking pathways, for example, the clathrin adapter protein complexes (AP-1, -2, and -3); ADP ribosylation factors (Arfs); Golgi-localized, γ -ear-containing, Arf-binding (GGA) proteins; the suppressor of cytokine signaling (SOCS1); Moloney leukemia virus 10, homolog (MOV10); and the soluble NSF attachment protein receptors (SNAREs).²⁹ Further study will be required to define the role of these proteins in HIV-1 assembly. A considerable amount of biochemical, microscopic, and pharmacologic data suggest that HIV-1 assembly takes place in lipid rafts, the cholesterol- and glycosphingolipid-enriched microdomains discussed earlier in the context of virus entry. Lipid rafts may stabilize Gag–membrane binding and facilitate assembly by serving as platforms for Gag–Gag interactions (for review see⁷⁸⁵).

FIGURE 49.30. Structure of a matrix (MA) trimer bound to membrane. At the top is depicted the lipid bilayer; myristate moieties are shown embedded in the bilayer. The helical C-terminal tail of MA is shown projecting away from the globular core. (Reprinted from Hill CP, Worthylake D, Bancroft DP, et al. Crystal structures of the trimeric human immunodeficiency virus type 1 matrix protein: implications for membrane association and assembly. *Proc Natl Acad Sci U S A* 1996;93:3099–3104, with permission. Copyright © 1996 National Academy of Sciences, USA.)

The MA domain not only functions in regulating Gag trafficking but also plays an important role in the incorporation of the viral Env glycoproteins into virions. This aspect of MA function will be discussed in more detail in the section on Env Glycoprotein Incorporation into Virions.

Capsid (CA): Gag Multimerization and Core Formation

The CA domain of Gag serves an important function in promoting virus assembly, and the mature CA protein forms the viral core after PR-mediated Gag processing. CA is composed of two structural and functional domains, the NTD and the CTD (Fig. 49.29C), which are connected by a short, flexible linker. This two-domain organization is a highly conserved feature among retroviral CA proteins. NMR and x-ray crystallographic data are available for both domains of HIV-1 CA^{246,262,531} (Fig. 49.31A). The NTD (residues 1 to 145) is highly helical, with an exposed, CypA-binding loop and an N-terminal β -hairpin.²⁴⁶ The CTD (residues 151 to 231) is also highly helical.²⁴⁷ The N-terminus of the CTD contains the major homology region (MHR), which, apart from the zinc-finger motifs in NC, is the only sequence in Gag that displays significant amino acid identity between divergent retroviral genera. Mutations within CA that disrupt HIV-1 replication elicit several distinct phenotypes: (a) defective immature virus particle production, (b) normal immature particle production but impaired formation of conical capsids, and (c) normal formation of immature particles and conical capsids but severely impaired infectivity.⁷⁷⁹ Mutations in the CTD often induce assembly defects, whereas changes in the NTD frequently inhibit proper virion maturation after release and severely impair infectivity.

Purified HIV-1 CA is capable of assembling into tubular or spherical particles^{199,281,778} *in vitro*. CA-NC fusion proteins form tubes *in vitro* at protein concentrations lower than those

required to assemble into similar structures with CA alone; in the case of CA-NC, tube formation appears to be dependent on the presence of nucleic acid.¹⁰¹ Interestingly, adding as few as four residues of MA to the N-terminus of CA converts *in vitro* particle assembly from tubes to spheres.⁷⁷⁸ This observation demonstrates that PR-mediated processing at the MA–CA junction causes a major refolding of the CA N-terminus and that this structural rearrangement plays a key role in promoting the morphologic changes that occur during core condensation.

In the tubes or cylinders assembled *in vitro*, CA is arranged in helical arrays in which the NTD forms hexameric rings that are linked into a continuous lattice by the CTD⁴⁴⁸ (Fig. 49.31B, C). Similar CA hexamers are visualized in cores obtained from purified HIV-1 virions,^{86,834} indicating that the CA arrays assembled *in vitro* reflect the physiologically relevant higher-order CA organization. As discussed earlier, in the immature VLP a large gap in the hexameric Gag lattice allows the lattice to curve and form a closed sphere. In the case of the mature capsid (note that the term *capsid* is used to refer to both the protein and the mature, conical core; here “CA” will be used to refer to the protein or the domain of Gag, while “capsid” will refer to the core), the formation of closed conical structures characteristic of mature lentiviral cores requires that 12 pentamers (*pentagonal defects* or *pentons*) be introduced into the hexagonal lattice, with 5 pentamers at the narrow end and 7 at the wider end (Fig. 49.31C). These cones are organized in a manner reminiscent of the fullerene structures formed by elemental carbon.²⁴⁸ Although the cores of other retroviruses are cylindrical or spherical, it has been suggested that all orthoretroviral cores are formed from similar hexagonal CA lattices and that their different shapes (cones, spheres, or cylinders) arise through differences in the spacing of the pentagonal defects.²⁴⁸ In support of this model, an HIV-1 CA mutant

FIGURE 49.31. Capsid (CA) structure. **A:** Model of the structure of a CA monomer. N-terminal domain (NTD), C-terminal domain (CTD), linker region, and cyclophilin A-binding loop are indicated. (**C** reprinted with permission from Pornillos O, Ganser-Pornillos BK, Yeager M. Atomic-level modelling of the HIV capsid. *Nature* 2011;469:424–427. Copyright © 2011, *Nature*.)

has been described that simultaneously assembles into cones, spheres, and cylinders,²⁵⁰ and an MLV CA NTD hexamer has been visualized by crystallography.⁵⁴² In addition to the CA hexamer structures mentioned earlier, structures of retroviral CA pentamers have also been determined by cryoelectron tomography¹⁰⁴ and x-ray crystallography.⁶¹⁰ These studies show that the hexamer and pentamer structures are quasiequivalent; only relatively subtle rearrangements are required for CA to shift from one to the other and analogous interaction interfaces are used in both structures. The hexameric lattice forms, and is stabilized by, three intermolecular CA–CA interfaces.⁶¹⁷

As mentioned previously, the HIV-1 CA binds members of the cyclophilin family of peptidyl-prolyl *cis-trans* isomerases.⁴⁷⁰ CypA is specifically incorporated into HIV-1 virions as the result of an interaction between CypA and a Pro-rich loop in the NTD that includes CA amino acid 90 (Figs. 49.29C and 49.31A).^{227,246,750} The relationship between CA–CypA binding and HIV-1 infectivity is complex and controversial; however, it appears that although CypA interacts with HIV-1 CA during assembly, most biologically significant interactions between CA and CypA occur postentry. At least under some circumstances, CypA binding to CA in the target cell helps to counteract restriction mediated by TRIM5 α and/or possibly other uncharacterized restriction factors.^{36,304,707}

The critical roles that CA plays both early and late in the HIV-1 replication cycle make it a promising target for the development of antiretroviral agents. Several CA-based inhibitors have been reported: one is a peptide, CAI, which disrupts HIV-1 assembly *in vitro* by binding a hydrophobic groove in the CA CTD.^{720,748} Although CAI is unable to enter cells and thus does not display antiviral activity, a technique known as hydrocarbon stapling was applied to this peptide to increase its cell permeability. The resulting circularized peptide is able to inhibit HIV-1 replication.⁸⁵⁰ A small molecule known as CAP1⁷⁴⁵ was identified in an *in silico* screen for CA-binding compounds and was found to disrupt assembly *in vitro* and in cells and to inhibit HIV-1 infectivity. CAP1 binds a hydrophobic cavity near the base of the CA NTD via an induced-fit mechanism whereby CAP1 binding displaces the aromatic ring of CA Phe-32.³⁸⁷ A different small molecule, binding a site on the CA NTD distinct from that occupied by CAP1, has been described.^{68,694} This compound inhibits both mature particle formation and virion infectivity, apparently by interfering with interactions between the CA NTD and CA CTD and by destabilizing the viral core. The identification of these CA-based inhibitors encourages efforts to develop highly specific and nontoxic small-molecule inhibitors of CA function that might be clinically active.

Nucleocapsid (NC): RNA Encapsidation, Gag Multimerization, and Nucleic Acid Chaperone Activity

The third major domain synthesized as part of the Gag precursor is NC (see Fig. 49.29D). NC is required for the specific encapsidation of full-length, unspliced (genomic) RNA into virions, and, like other Gag domains, it serves multiple roles during the virus replication cycle. All orthoretroviral NC proteins contain one or two zinc-finger motifs. Unlike most cellular zinc-finger domains, retroviral NC zinc fingers are of the CCHC type (Cys- X_2 -Cys- X_4 -His- X_4 -Cys, where X is any amino acid). HIV-1 NC contains two zinc-finger motifs that bind zinc tightly both *in vitro* and in virions^{55,714} and two clusters of basic residues flanking the first zinc finger.

NC engages in both sequence-specific and sequence non-specific interactions with nucleic acid. In general, the sequence-specific interactions involve the zinc fingers in conjunction with the basic residues, whereas nonspecific interactions are driven largely by the positive charge conferred by the basic residues. NMR data indicate that the two HIV-1 NC zinc fingers are brought together into a central globular domain by a highly basic linker domain (Fig. 49.32), which appears to be very

FIGURE 49.32. Complex between nucleocapsid (NC) and stem-loop 3 (SL3) of the human immunodeficiency virus 1 (HIV-1) packaging signal. The two zinc ions coordinated by the zinc-finger domains are shown as gray balls. Color scheme: N-terminal 3_{10} helix, pink; N-terminal zinc finger, cyan; linker, red; C-terminal zinc finger, green; cysteine and histidine side chains, yellow and cyan, respectively. (Reprinted from Turner BG, Summers MF. Structural biology of HIV. *J Mol Biol* 1999;285:1–32, by permission of the publisher Academic Press.)

flexible.^{538,732} Mutations that abrogate zinc binding by retroviral NC abolish genome encapsidation and virus infectivity.^{272,518} As discussed earlier, the specificity of HIV-1 genome encapsidation results in part from an interaction between NC and an approximately 120-nt sequence located between the 5' LTR and the Gag initiation codon. This sequence, variously known as the packaging signal, encapsidation element, or ψ -site, folds into a series of four stem-loops (SL1 to SL4) (see Fig. 49.7; for review on RNA encapsidation, see⁴⁶⁶). It appears that this secondary structure, rather than the primary nucleotide sequence itself, confers RNA encapsidation specificity. NC reportedly binds SL2 and SL3 with the highest affinity. Structures for SL2 and SL3 in complex with NC were solved in early studies by NMR spectroscopy.^{15,172} These structures demonstrate the involvement of both basic and zinc-finger residues in the NC/ ψ interaction. Despite some important similarities, key structural differences exist between NC–SL2 and NC–SL3 interactions, illustrating the flexibility of NC in binding to different RNA targets. Over the past decade, the structures of many small HIV-1 RNA fragments have been solved (reviewed in^{15,172}), and recently, the secondary RNA structure of the entire HIV-1 genome was determined by SHAPE technology⁷⁹¹ (see section on Genomic Organization of HIVs). It should be emphasized that the HIV-1 genomic RNA likely adopts a range of distinct conformations⁴⁶⁶; defining which conformations are required to promote specific steps in the virus replication cycle remains a challenging problem for further investigation.

Viral genomic RNA in virions is dimeric, and RNA labeling data support the presence of one RNA dimer per virion.¹²⁰ Although some studies reported that dimerization takes place after RNA encapsidation, compelling genetic evidence from studies that used recombination rates to measure RNA co-packaging supports the hypothesis that Gag selects RNA dimers for packaging.^{126,534} In the MLV system, it has been reported that RNA dimerization exposes a high-affinity binding site for NC, thus helping to explain why dimeric RNAs are packaged selectively over monomers.^{156,260,528} In the case of HIV-1, NMR analysis revealed that a stem-loop encompassing the Gag AUG start codon base pairs with a sequence upstream in U5. This interaction is proposed to expose the DIS, thereby promoting RNA dimerization and increasing NC binding.⁴⁶⁵ This structural switch provides a mechanism for regulating translation, RNA dimerization, and packaging.

Live-cell imaging demonstrates that HIV-1 genomic RNA is highly dynamic within cells but becomes stabilized at the plasma membrane through its interactions with a small number of Gag molecules.³⁶⁹ Thus, the initial Gag–RNA complex likely serves as the focal point for subsequent VLP assembly. In the absence of Gag expression or an intact ψ -signal, HIV-1 RNA is not observed at the plasma membrane.³⁸⁸ Consistent with these findings, Gag–RNA-binding assays coupled with membrane flotation analysis suggest that initial Gag–RNA contacts take place in the cytoplasm and that RNA associated with monomeric or dimeric Gag traffics to the plasma membrane where assembly proceeds.⁴¹⁴

NC–RNA interactions are critical for promoting Gag multimerization; thus, many NC mutations cause defects in virus assembly and release. The role of RNA in assembly is primarily to provide a template along which molecules of Pr55^{Gag} can align and pack. The RNA with which NC interacts need not be viral genomic RNA; expression of retroviral Gag proteins in the

absence of packageable viral RNA leads to efficient assembly, apparently through the use of cellular RNAs as a scaffold.⁵⁴⁹

In addition to its roles in RNA encapsidation and Gag assembly, other functions for HIV-1 NC have been observed. Many of these are critical for efficient reverse transcription and are attributed to the nucleic acid chaperone activity of NC.^{440,623} This property enables NC to catalyze the refolding of nucleic acid molecules into structures with the most thermodynamically favorable conformation (i.e., the greatest number of base pairs) (for reviews see^{440,623}). The nucleic acid chaperone activity of NC evidently requires that NC molecules coat nucleic acid at near-saturating levels of approximately one molecule of protein per five to eight nucleotides. NC, or the NC domain of Pr55^{Gag}, contributes to placement of the tRNA^{Lys3} primer on the pbs (see section on Reverse Transcription), unwinding of the tRNA during the initiation of reverse transcription,²⁹⁷ increased efficiency of minus-strand transfer by increasing the annealing of complementary R regions, removal of annealed RNA fragments during minus-strand strong-stop DNA synthesis, destabilization of nucleic acid secondary structure during both minus- and plus-strand DNA synthesis, and stimulation of plus-strand transfer by promoting the removal of the tRNA primer and annealing of the pbs sequence in plus-strand strong-stop DNA to its minus-strand DNA complement.⁴⁴⁰ The nucleic acid chaperone activity of NC relies on two seemingly opposing properties: the ability to weakly destabilize nucleic acid duplexes (which is central to melting secondary structures that would interfere with reverse transcription) and the ability to aggregate nucleic acids (which promotes placement of the tRNA primer on the pbs and facilitates annealing reactions during strand transfers). The duplex-destabilizing activity of NC is primarily mediated by the zinc fingers and is due to a preferential binding of the fingers to single-stranded nucleic acid.^{15,16} The ability of NC to aggregate nucleic acids appears to be at least partially due to its highly basic nature.

The nucleic acid chaperone activity of NC has been demonstrated not only in *in vitro* assays⁴⁴⁰ but also by studying the effects of NC mutation on reverse transcription and virus infectivity in cells.^{53,89,270,271,744} Mutations in HIV-1 NC impair infectivity by destabilizing newly reverse-transcribed viral DNA.⁵³ Studies performed with MLV demonstrated that changing the single CCHC zinc-finger motif to CCCC or CCHH had no effect on zinc binding, tRNA incorporation, RNA encapsidation, or RNA maturation but profoundly impaired virus infectivity.²⁷⁰ Examination of viral DNA in mutant-infected cells revealed that full-length, circular DNA products were formed inefficiently and that a variety of mutations were present at the DNA ends.²⁷⁰ Such aberrations, if present at the termini of linear DNAs, would render these DNAs unsuitable for integration. Analogous mutations in the zinc fingers of the HIV-1 NC have been reported^{89,271,744}; these changes resulted in defects in reverse transcription, leading to a lack of circular DNA production, degradation of the viral DNA ends, and impaired virus infectivity. NC has also been observed to promote integration *in vitro*^{107,254}; mutations in the HIV-1 NC zinc fingers interfere with IN-mediated end processing, leading to defects in integration in infected cells.⁸⁹

Because NC participates in multiple steps in the virus life cycle, it represents an attractive target for antiviral agents. Although many cellular proteins contain zinc fingers, the retroviral CCHC-type zinc-finger motif is relatively uncommon,

and a number of compounds have been described that appear to selectively impair NC function without causing significant cytotoxicity (for review see^{550,761}). For example, mild oxidizing agents such as 2,2'-dithiopyridine (aldrithiol-2, or AT-2) cause zinc to be "ejected" from the zinc fingers and lead to extensive protein cross-linking.^{627,628} Alkylating agents such as N-ethylmaleimide (NEM) react with zinc-bound thiols in NC and inactivate virus infectivity.⁵³⁵ Compounds that induce the ejection of zinc from NC include the S-acyl-2-mercaptobenzamide thioesters (SAMTs),³⁵⁸ which possess a novel mechanism of action in cells: the thiol generated by the reaction between NC and SAMT is acylated in the cell to regenerate an active thioester.⁵²² This recycling process likely adds to the potency and stability of the inhibitor. Although clinically effective NC inhibitors have not yet been identified, this appears to be a promising area for future research.

p6: Virus Release and Vpr/Vpx Incorporation

In addition to the MA, CA, and NC proteins described earlier, HIV-1 encodes a Pro-rich, 6-kD protein, known as p6, at the C-terminus of Pr55^{Gag} (see Fig. 49.29E). Deletion of p6 significantly disrupts HIV-1 particle production by blocking a late step in the budding process.²⁷⁵ Particles assembled from p6 mutants display a release defect characterized by a striking accumulation of tethered virions at the plasma membrane (Fig. 49.33). The virus release function of p6 maps to a highly conserved Pro-Thr-Ala-Pro (PTAP) motif near the N-terminus of p6.^{179,333}

Mutational analyses of the *gag* genes of a number of retroviruses revealed the presence of motifs that, like PTAP of p6, promote the release of virions from the plasma membrane. These short sequences have been termed *late* domains to reflect their role late in the budding process (for reviews see^{58,177,541,611}). Three general classes of retroviral late domains have been identified: PTAP (or PSAP), Pro-Pro-Pro-Tyr (PPPY), and Tyr-Pro-X_n-Leu (YPX_nL, where X is any amino acid and n = 1 to 3 residues). Specific examples of viruses in which these late domains are located include PTAP in p6 of primate lentiviral Gag, the MA domain of HTLV-1, and pp16 of Mason-Pfizer monkey virus (M-PMV); PPPY in p12 of MLV, p2b of Rous sarcoma virus, pp16 of M-PMV, and the MA domain of HTLV-1; and YPX_nL in the p9 domain of EIAV Gag and p6 of primate lentiviral Gag. In each case, mutation of these motifs disrupts virus budding and release. Interestingly, similar motifs function to promote the release of other enveloped viruses (e.g., the *Filoviridae* and *Rhabdoviridae*).

Numerous lines of evidence support the hypothesis that retroviral late domains function by interacting with components of the cellular endosomal sorting machinery.^{177,541} Cargo proteins ultimately destined for the vacuole in yeast and the lysosome in mammalian cells are recognized sequentially by four multiprotein complexes, termed ESCRT-0, -I, -II, and -III (for endosomal sorting complex required for transport-0, -I, -II, and -III).³⁸⁰ These cargo proteins are initially sorted into vesicles that bud inwardly into late endosomes to generate MVBs. ESCRT machinery also plays a key role in membrane fission during the abscission step of cytokinesis.^{106,539} It is noteworthy that retrovirus budding and release from the plasma membrane involve a membrane budding and scission event that is topologically equivalent to budding and scission steps that occur during MVB formation and cell abscission; that is, these events are oriented away from the cytosol. Thus, retroviruses appear to have evolved the ability to usurp cellular

FIGURE 49.33. Morphology of wild-type (WT) versus p6-deleted human immunodeficiency virus 1 (HIV-1) visualized by thin-section transmission electron microscopy (EM). Note the presence of released, mature particles in the WT micrograph (left panel) and tethered, immature particles in the p6-mutant micrograph (right panel). (Courtesy of Kunio Nagashima.)

budding machinery to promote their release from the plasma membrane (Fig. 49.34). While the molecular details of ESCRT function are still being elucidated, it appears that ESCRT-0 first associates with endosomal membrane and cargo protein via phosphatidyl inositol-3-phosphate and ubiquitin binding, respectively, and subsequently recruits downstream ESCRTs (I, II, and III) to the membrane. *In vitro* reconstitution studies suggest that ESCRT-I and -II provide the driving force for membrane budding, whereas ESCRT-III plays a central role in the membrane scission event.^{339,810,811} The adenosine triphosphatase (ATPase) Vps4 is also implicated in membrane scission and catalyzes the recycling of ESCRT complexes back to the cytosol after membrane scission is completed. Interestingly, HIV-1 budding and release appear to require only a subset of ESCRT machinery; ESCRT-0, ESCRT-II, and some ESCRT-III components are not required^{422,540} (Fig. 49.34).

A connection between the endosomal sorting pathway and HIV-1 budding was first suggested by the observation that the ESCRT-I component Tsg101 interacts with p6, and that this interaction is dependent on the PTAP motif.^{257,774} The functional significance of this interaction was supported by the finding that siRNA-mediated depletion of Tsg101 disrupts HIV-1 release,²⁵⁷ as does overexpression of the N-terminal, Gag-binding domain of Tsg101 (TSG-5').¹⁷⁸ Inhibition of release imposed by both Tsg101 depletion and overexpression of TSG-5' is specific for PTAP-dependent budding, as the release of the PPPY-bearing MLV is unaffected.^{178,257} The significance of p6-Tsg101 binding in HIV-1 release was also supported by the finding that fusing Tsg101 directly to the C-terminus of Gag rescued a p6 late-domain defect, indicating that the primary role of p6 in virus release is to bind Tsg101.⁵⁰¹ Broad disruption of the endosomal sorting pathway by overexpressing a

FIGURE 49.34. Role of endosomal sorting complex required for transport (ESCRT) machinery in virus budding (A), multivesicular body (MVB) biogenesis (B), and the abscission step of cytokinesis (C). ESCRT-I, -II, and -III are labeled. While not explicitly labeled as such, the STAM/HRS complex is often referred to as ESCRT-0. Note that virus budding does not appear to use ESCRT-II and requires only a subset of ESCRT-III proteins. (Reprinted from Balasubramaniam M, Freed EO. New insights into HIV assembly and trafficking. *Physiology [Bethesda]* 2011;26:236–251, with permission.)

dominant-negative mutant of the ATPase Vps4 globally inhibits the budding of a number of retroviruses, suggesting that most, if not all, retroviruses depend on the ESCRT apparatus for their release.^{177,541} Whereas PTAP late domains function by interacting with the ESCRT-I component Tsg101, the YPX_nL-type motif of EIAV interacts with the ESCRT-associated factor Alix (formerly AIP1).^{500,723,780} Alix, although not a component of an ESCRT complex, can bridge ESCRT-I and ESCRT-III by interacting with both Tsg101 and one of the ESCRT-III components^{500,723,780} (Fig. 49.34). PPPY-type late domains bind members of the Nedd4 family of E3 ubiquitin ligases.^{58,177,541}

Although under most conditions PTAP serves as the dominant HIV-1 late domain, p6 also bears an Alix-binding YPX_nL motif (Fig. 49.29E).^{500,723,780} The presence of this alternative site for interaction between HIV-1 Gag and the ESCRT machinery suggests that under some circumstances Alix plays a role in HIV-1 budding and release. Indeed, if the PTAP motif is eliminated by mutation, Alix overexpression partially rescues virus release.⁷⁶² Furthermore, mutation of the Alix binding site in p6 induces significant virus replication defects in T cells and macrophages. Simultaneous elimination of both Tsg101 and Alix binding sites in p6 abolishes virus replication.²³⁹ These findings suggest some degree of functional redundancy between PTAP and YPX_nL motifs in HIV-1 replication. In addition to binding the YPX_nL motif in HIV-1 p6, Alix has also been reported to interact with the NC domain of Gag.^{196,606,607}

Recent advances in live-cell imaging technology have provided new insights into the role of ESCRT machinery in cytokinesis and HIV-1 release. Total internal reflection fluorescence (TIRF) microscopy and fluorescently tagged Gag and ESCRT components were used to follow the recruitment of ESCRT machinery during retrovirus assembly and release.³⁷⁰ Gag assembly was typically completed within ~5 to 10 minutes of the initial appearance of an individual Gag punctum.^{349,369} For both HIV-1 and EIAV, ESCRT-III components and Vps4 were transiently recruited late in this process, concomitant with the completion of assembly. In contrast, Alix accumulated earlier in the EIAV Gag assembly process and its accumulation appeared to coincide with Gag recruitment.³⁷⁰ As expected, late domain mutation largely ablated ESCRT-III recruitment but did not affect the kinetics of assembly.^{349,370} The sequential recruitment of ESCRT machinery to the site of membrane fission is also supported by time-lapse imaging of the abscission step of cytokinesis.²⁰² ESCRT-I and -III components were observed to be recruited to ring-like structures in the intercellular bridge separating the two daughter cells undergoing cytokinesis. Subsequent recruitment of ESCRT-III and Vps4 to the constricted region at which membrane separation occurs was followed immediately by abscission. These observations are consistent with a direct role for ESCRT-III and Vps4 in membrane scission.

In addition to its role in promoting virus budding, p6 functions to direct the incorporation of Vpr and Vpx into virions.^{587,818} In the case of HIV-1, the binding site for Vpr overlaps with the sequence responsible for p6 association with Alix (Fig. 49.29E).

Env Glycoprotein Incorporation into Virions

The mechanism by which HIV-1 Env glycoproteins are incorporated into budding virus particles remains incompletely characterized. Several models for Env incorporation can be posulated¹¹⁷: (a) passive incorporation, in which the simple pres-

ence of Env glycoproteins in the plasma membrane is sufficient to allow them to be packaged into budding virus particles; (b) direct Gag–Env interaction, in which direct contacts between the cytoplasmic tail of gp41 and the membrane-proximal portion of Gag (i.e., the MA domain) are required for the active recruitment of Env into virions; (c) Gag–Env co-targeting, whereby Gag and Env traffic to a common site on the plasma membrane (e.g., a lipid raft or other type of membrane microdomain), thus concentrating Env at sites of Gag assembly; and (d) indirect Gag–Env interaction, according to which a host cell protein serves to link the gp41 cytoplasmic tail with the MA domain of Gag. Data in the literature can be invoked to support each of these models. In some cell lines, gp41 lacking the cytoplasmic tail is efficiently incorporated into virions. The Env proteins from heterologous viruses (e.g., MLV Env and vesicular stomatitis virus glycoprotein [VSV-G]) can be packaged into HIV-1 particles (a process known as pseudotyping), and host cell membrane proteins are also present within the viral envelope. However, despite this apparently nonspecific incorporation, several lines of evidence suggest that HIV-1 Env glycoproteins are actively recruited into virions via direct interactions between Env and MA: (a) mutations in the MA domain of Gag can block HIV-1 Env incorporation,^{190,233,839} and this incorporation defect can be reversed by pseudotyping virions with heterologous Env glycoproteins or by removing the gp41 cytoplasmic tail^{231,233,485}; (b) HIV-1 Env directs basolateral budding of Gag in polarized epithelial cells^{460,578}; and (c) a single amino acid change in MA reverses an Env-incorporation defect caused by a small deletion in the gp41 cytoplasmic tail.⁵⁴⁶ Although in some cell lines truncation of the gp41 cytoplasmic tail has little effect on Env incorporation, in most cell lines and in primary cell types, including PBMCs and MDMs, gp41 truncations severely disrupt Env incorporation.⁵⁴⁷ Thus, it is clear that the gp41 cytoplasmic domain plays an important role in the incorporation of Env into HIV-1 particles. The cell-type dependence of this function suggests the involvement of host cell factors or structures; these could be a common site or microdomain to which Gag and Env are co-targeted (e.g., a lipid raft) or a cellular protein that forms a bridge between MA and the gp41 cytoplasmic tail. As mentioned earlier, both Gag and Env localize to cholesterol- and sphingolipid-enriched lipid raft microdomains in the plasma membrane,⁷⁸⁵ and several host cell proteins have been proposed to bind Gag and/or Env to facilitate Env incorporation.¹¹⁷ The aforementioned observation that MA mutations can block the incorporation of full-length Env into virions and that gp41 cytoplasmic tail deletions can rescue this incorporation defect suggests that incorporation of full-length Env requires active recruitment (or at least accommodation) by MA, whereas incorporation of truncated HIV-1 Env, or heterologous glycoproteins bearing short cytoplasmic domains, is a more passive process. At this time, however, a detailed view of the host cell's role in promoting Env incorporation is lacking.

Virus Maturation: Protease (PR)

Early pulse-chase studies performed with avian retroviruses demonstrated that retroviral Gag proteins are initially synthesized as polyprotein precursors that are cleaved to generate smaller products.⁷⁷⁶ Subsequent studies revealed that the processing function is provided by the viral PR, and that proteolytic digestion of the Gag and Gag-Pol precursors is essential for virus infectivity.^{152,378} Sequence analysis of retroviral PRs

FIGURE 49.35. Structure of the human immunodeficiency virus 1 (HIV-1) protease (PR) dimer uncomplexed (A) or complexed (B) with the PR inhibitor Ro-31-8558. The following domains are indicated in the first half of the molecule: β -strands a (residues 1 to 4), b (residues 9 to 15), c, and d (residues 30 to 35). The active-site residues are at positions 25 to 27. The second half of the molecule is structurally related to the first half, with the following domains indicated: β -strands a' (residues 43 to 49), b' (residues 52 to 66), c' (residues 69 to 78), d' (residues 83 to 85), and helix h' (residues 86 to 94). The inner portion of the dimer interface is formed by β -strand q (residues 95 to 99). (Modified by Jerry Alexandratos from Wlodawer A, Erickson JW. Structure-based inhibitors of HIV-1 protease. *Annu Rev Biochem* 1993;62:543–585.)

indicated that they are related to cellular “aspartic” proteases such as pepsin and renin (for review see¹⁶⁸). Like these cellular enzymes, retroviral PRs use two apposed Asp residues in the active site to coordinate a water molecule that catalyzes the hydrolysis of a peptide bond in the target protein. However, unlike the cellular aspartic proteases, which function as pseudodimers (using two folds within the same molecule to generate the active site), retroviral PRs function as true dimers. X-ray crystallographic data from HIV-1 PR^{424,556,809} indicate that the two monomers are held together in part by a four-stranded, antiparallel β -sheet derived from both N- and C-terminal ends of each monomer (Fig. 49.35). The substrate-binding site is located within a cleft formed between the two monomers. Like their cellular homologs, the HIV-1 PR dimer contains flexible “flaps” that overhang the binding site and may stabilize the substrate within the cleft; the active-site Asp residues lie in the center of the dimer. Although some limited amino acid homology is observed surrounding active-site residues, the primary sequences of retroviral PRs are highly divergent, yet their structures are remarkably similar.

The first cleavage events catalyzed by retroviral PRs during or immediately after virion release from the cell are likely intramolecular⁵⁹⁹ and serve to liberate PR from the Gag-Pol precursor. As mentioned earlier, after the release of PR from the Gag-Pol precursor, the dimeric enzyme cleaves a number of sites in both Gag and Gag-Pol (see Fig. 49.6). The efficiency with which PR cleaves the individual target sites in Gag and Gag-Pol varies widely and is influenced by two major factors: the amino acid sequence at the site of cleavage and the context (i.e., degree of exposure or accessibility) of the cleavage site. The proteolytic processing of model proteins and substrate analogs by HIV-1 PR indicates that the binding cleft can accommodate a peptide of approximately seven residues in length, and synthetic peptides of this size are cleaved *in vitro*.⁶¹ As a consequence of the relatively divergent PR target sequences present in Gag and the varying efficiencies with which these sites serve as substrates for PR activity, Gag cleavage takes place as an ordered,

step-wise cascade. Processing at the N-terminus of NC is the most rapid *in vitro*, whereas the cleavage converting CA-SP1 (p25) to CA (p24) is the slowest. Mutations in Gag that disrupt the ordered nature of PR-mediated processing severely disrupt virus assembly or subsequent maturation. Furthermore, HIV-1 mutants engineered to overexpress PR exhibit rapid, premature processing of Gag and Gag-Pol polyproteins and a block in virus production.⁴⁰⁷ Thus, the activation of PR must be tightly controlled to prevent significant processing prior to the completion of assembly. Although the high concentration of Gag and Gag-Pol precursors achieved upon particle assembly undoubtedly facilitates activation of PR, factors that regulate retroviral PR activity remain to be fully defined.

PR cleavage of the Gag and Gag-Pol precursors leads to a dramatic change in virion morphology, a process known as maturation. Immature retroviral particles (e.g., those produced in the presence of PR inhibitors or an inactive PR) appear doughnut-shaped by thin-section EM. In contrast, mature HIV-1 virions contain conical cores. As mentioned earlier, cryoelectron tomography studies have shown that in immature virions Gag precursors are aligned in a rod-like fashion like spokes on a wheel, with the N-terminal MA domain associated with the viral membrane and the C-terminal domains projecting inward toward the center of the virion.^{243,815,835} Cleavage of Gag by PR releases CA, NC, and p6 from their attachment (via MA) to the lipid and allows CA to form a shell around the NC–RNA complex. Formation of the conical core likely involves a reassembly process rather than a concerted condensation reaction.⁴² Gag in the immature virus particle and CA in the mature core form a hexameric lattice with a unit cell spacing of ~8 nm in the case of the immature particle and ~9 nm in the case of the mature CA lattice.

Competitive inhibitors of HIV-1 PR function have proven to be highly effective antiretroviral drugs, particularly when used in combination with RT inhibitors. The development of PR inhibitors represents a classic example of structure-based drug design; detailed knowledge of the topology of the substrate-binding site, the enzyme–substrate interaction, and

the chemistry of the cleavage reaction enabled investigators to synthesize a large number of inhibitors that potently inhibit PR in culture at nanomolar concentrations. The earliest PR inhibitors were small oligopeptide derivatives that mimicked PR target sequences but contained nonhydrolyzable groups at the P1 and P1' positions flanking the scissile bond that PR would normally cleave. The early, peptide-based inhibitors were subsequently modified to improve stability and bioavailability, and the structure of the PR active site was used to design novel inhibitory compounds.⁸⁰⁹ When PR inhibitors are used to treat HIV-infected patients, virus loads decline precipitously, but drug-resistant variants soon emerge. Sequencing of the PR coding region of drug-resistant variants often reveals consistent changes. For example, saquinavir escape mutants frequently contain changes at PR residue 48 and/or 90; ritonavir resistance is often associated with mutations at PR residue 82. The initial changes that confer drug resistance generally result in only partial resistance and may be accompanied by decreased “fitness” (i.e., impaired PR function relative to WT in the absence of drug). With time, however, additional changes take place within PR that increase resistance and improve fitness. Unfortunately, mutations that arise in the presence of one inhibitor frequently induce at least partial resistance to others, a phenomenon known as cross-resistance. In addition to changes in PR, mutations that affect the natural PR targets of the enzyme (i.e., the Gag and Pol cleavage sites) have been observed.¹⁹⁴

The highly ordered nature of Gag processing and the strict dependence on complete processing for proper virion maturation make the Gag processing cascade a potential target for drug development. Indeed, the betulinic acid derivative dimethylsuccinyl betulinic acid (PA-457 or DSB, also known as bevirimat) potently inhibits HIV-1 infectivity by targeting a late Gag processing event: the cleavage of the CA-SP1 processing intermediate to mature CA.^{446,858} By specifically disrupting this step in Gag processing, treatment of virus-expressing cells with bevirimat leads to the formation of poorly infectious viral particles with aberrantly condensed cores. Selection in culture gives rise to bevirimat-resistant isolates that contain single amino acid substitutions flanking the CA/SP1 cleavage site.^{3,446,858} In patients, bevirimat can lead to significant reductions in viral loads,^{629,705} providing proof of concept that compounds capable of disrupting specific steps in Gag processing could be clinically effective against HIV-1. In the case of bevirimat, however, polymorphisms in SP1 downstream from the cleavage site reduce susceptibility to the compound in many patients.^{5,109,629} A second, structurally distinct maturation inhibitor (known as PF-46396) that blocks CA-SP1 processing has been described.⁶⁷ Interestingly, several of the mutations that confer resistance to PF-46396 map to regions of CA far upstream of the CA-SP1 cleavage site.⁷⁸⁷ These observations suggest that bevirimat and PF-46396 may occupy distinct binding sites on the assembled Gag complex, the presumed target of these compounds. In addition to compounds that block virus maturation by interfering with specific step(s) in Gag processing, condensation of a functional viral core can also be inhibited by molecules that bind the CA domain of Gag. Several compounds in this class are discussed in the CA section.

The Accessory Proteins

In addition to the viral structural proteins (Gag and Env), the *pol*-encoded enzymes (PR, RT, and IN), and the regula-

TABLE 49.3 HIV/SIV Accessory Proteins

Protein	Major proposed functions
Vif	Inactivation of antiviral activity of APOBEC family of cytidine deaminases

PIC, preintegration complex; SAMHD1, SAM domain and HD domain-containing protein 1; MHC-I, major histocompatibility complex I.

tory proteins (Rev and Tat), the HIV genome encodes several “accessory” proteins: Vif, Vpu, Vpr, Nef, and Vpx (in the case of HIV-2) (see Fig. 49.6). Early studies indicated that disruption of the ORFs for these proteins had little or no effect on virus replication in culture; indeed, laboratory-adapted virus isolates often acquire inactivating mutations in several of these genes. However, more recent tissue culture and *in vivo* experiments revealed a strong requirement for these gene products in efficient virus replication and disease induction. Remarkably, three of the four HIV-1/SIV accessory proteins (Vif, Vpu, and Vpr/Vpx) serve as adaptors to connect cellular substrates to the host cell proteasome machinery. These viral proteins function in part to counteract components of the cellular innate immune response that evolved to restrict retroviral infection. A summary of the major proposed functions of the HIV-1 accessory proteins is presented in Table 49.3.

Vif

As discussed earlier, the Vif protein derives its name (virus infectivity factor) from the observation that it plays a role in promoting virus infectivity. The finding that the requirement for Vif is producer-cell dependent suggested that Vif interacts with a host factor during virus assembly. The host factor in question was subsequently identified as the DNA cytidine deaminase APOBEC3G. The ability of Vif to counter the antiviral activity of APOBEC3G and related host enzymes is discussed in detail in the section on APOBEC3G and Family Members.

Vpr

The *vpr* gene encodes a 14-kD, 96-amino acid protein that is incorporated at high levels into virus particles.^{143,841} Virion incorporation is mediated through an interaction with a (Leu-X-X)₄ motif near the C-terminus of the p6 domain of Gag (Fig. 49.29E).^{403,468,841} The NMR structure of Vpr⁵³⁶ reveals

the presence of three α -helices folded around a hydrophobic core. The N- and C-termini of the protein are flexible. Although Vpr has little influence on HIV replication kinetics in proliferating PBMCs or T-cell lines in culture, in nondividing MDMs its effects are more substantial. Several lines of evidence indicate that Vpr is also required for efficient replication *in vivo*: Vpr mutations are observed in HIV-1 strains isolated from long-term nonprogressors,⁷¹⁰ and deletion of Vpr modestly decreases SIV pathogenicity in rhesus macaques.⁴²¹ Vpr has been reported to (a) stimulate gene expression driven by the HIV-1 LTR and enhance transcription of cellular genes, (b) promote transport of the viral PIC to the nucleus early postinfection, (c) arrest infected cells in the G₂ phase of the cell cycle, (d) induce apoptosis, and (e) modulate mutation rates during reverse transcription through interactions with uracil DNA glycosidases.

Early studies reported that Vpr weakly transactivates expression from the HIV-1 LTR,¹⁴³ potentially through Vpr interactions with Sp1,^{665,790} TFIIB,^{6,394} and/or TFIID.³⁹⁴ Vpr has also been reported to stimulate gene expression from cellular promoters, in part by interacting with the glucocorticoid receptor and enhancing its activity.³⁹⁴ Binding between Vpr and co-activators p300/CREB-binding protein may play a role in Vpr-mediated activation of both the viral LTR and cellular promoters.³⁹⁵

High levels of virion incorporation suggest a role for Vpr early in the virus life cycle prior to *de novo* gene expression. The observations that deletion of Vpr significantly reduces virus replication in terminally differentiated, nondividing MDMs,³⁰ that the HIV-1 PIC contains Vpr,³¹¹ and that Vpr localizes to the nucleus in HIV-1-infected or Vpr-expressing cells⁴⁶⁹ suggested that Vpr participates in the nuclear import of the HIV-1 PIC. However, deletion of Vpr does not block HIV-1 replication in terminally differentiated MDMs²³⁰ or other nondividing cells,⁸²⁵ and an MLV/HIV chimera lacking Vpr still infects nondividing cells.⁸²⁴

A major and well-validated activity of Vpr is the arrest of cells in the G₂ phase of the cell cycle (for review see⁶⁰³). Cell cycle arrest reportedly occurs within hours of infection and is not blocked by antiviral agents, suggesting that arrest can be initiated by virion-associated Vpr carried into the cell during infection.⁶⁰⁵ One possible scenario to explain the disruption of the cell cycle by Vpr is that it serves to link a still-unidentified cellular protein (or proteins) to the proteasomal degradation machinery. An early report identified a Vpr-binding protein (VprBP)⁸⁵³ that was later shown to bind damaged-DNA specific binding protein 1 (DDB1), which in turn associates with cullin 4 (CUL4).^{327,429,677} The interaction between Vpr and VprBP—subsequently renamed DCAF1 (DDB1- and CUL4-associated factor 1)—allows Vpr to recruit the unidentified substrate into the E3 ubiquitin ligase complex, presumably resulting in its ubiquitination and proteasome-mediated degradation. A role for Vpr–DCAF1 binding in cell cycle arrest is supported by the observations that this function of Vpr is abrogated by mutation of the DCAF1 binding site of Vpr or DCAF1 depletion.⁴²⁹ Early studies suggested that disruption of the cell cycle by Vpr involves inactivation of the p34cdc2–cyclin B kinase complex.^{310,621} This inactivation may arise through Vpr-induced modulation of host factors such as PP2A, Wee1, Myt1, and Cdc25C, which function upstream of the p34cdc2–cyclin B kinase complex (for review see⁶⁰³). A number of additional Vpr-interacting

proteins have been suggested to play a role in cell cycle arrest. These include HHR23A (the human homolog of the yeast repair protein Rad23),⁸⁰⁷ the DNA damage signaling protein ATR,⁶⁴¹ hVIP/MOV34,⁴⁷⁹ p21^{WAF154} and the family of factors known as 14-3-3 proteins, which function at several stages to regulate the cell cycle.³⁹⁶ Recent work has proposed that Vpr induces cell cycle arrest by recruiting the DDB1–CUL4 ubiquitin ligase complex to chromatin-associated nuclear foci, leading to proteasome-mediated degradation of a chromatin-bound cellular factor, and activation of ATR (ataxia telangiectasia mutated and Rad3 related), a protein involved in regulating the G₂/M checkpoint.⁴⁰ Although the precise mechanism and biological implications of Vpr-induced cell cycle arrest remain unclear, it has been proposed that increased HIV-1 LTR-driven transcription in the G₂ phase of the cell cycle could provide a rationale for the evolution of a Vpr cell cycle arrest function.²⁶⁵ The ability of Vpr to induce cell cycle arrest not only in mammalian cells but also in yeast⁴⁷³ implies the involvement of highly conserved cellular factors in this phenomenon.

Vpr was observed in yeast two-hybrid studies to interact with uracil DNA glycosylase-2 (UNG-2).⁷⁶ The ability of UNG-2 to remove uracils from DNA led to the suggestion that Vpr-mediated UNG-2 incorporation into virions could modulate viral mutation rates during reverse transcription by limiting dUTP misincorporation.^{122,490} However, subsequent studies showed that Vpr binding leads to UNG-2 degradation by linking UNG-2 to DCAF-1 and the CUL4–E3 ubiquitin ligase complex and, indeed, that Vpr(+) virions contain lower amounts of UNG-2 than Vpr(–) particles.^{7,677,678} While the biological consequences of Vpr-mediated UNG-2 degradation remain controversial, UNG-2 provides a clear example of a host cell factor that is linked by Vpr to the DCAF-1/CUL4/ubiquitin ligase complex for proteasomal degradation.⁷

Evidence from many laboratories has suggested that Vpr induces apoptosis through both caspase-dependent and caspase-independent pathways (for review see⁵⁵¹). It remains unclear whether this activity of Vpr also relates to its ability to hijack the host ubiquitination machinery. It has been postulated that Vpr-mediated apoptosis is a consequence of prolonged cell cycle arrest,¹⁷ suggesting a link between these two well-established Vpr activities.

The incorporation of Vpr into virions and its association with the reverse transcription complex and PIC postentry have provided the basis for useful tools in the study of entry and postentry events. GFP-Vpr fusion proteins have allowed investigators to track the movement of reverse transcription complexes early after infection, revealing that these complexes use dynein and the microtubule network to traffic toward the nucleus.⁵¹² The incorporation of a Vpr- β -lactamase chimera into virions and the subsequent delivery of the enzymatic activity of β -lactamase into target cells upon virion-cell fusion have provided a sensitive virus entry assay.¹¹⁰

Vpx

Members of the HIV-2/SIV_{sm}/SIV_{mac} lineage of primate lentiviruses carry an additional gene known as *vpx*. The *vpr* and *vpx* genes are highly related and it has been proposed that *vpx* likely arose by acquisition of the SIV_{agm} *vpr* gene by non-homologous⁶⁹¹ or homologous⁷⁵⁷ recombination.

Like Vpr, Vpx is incorporated at high levels into virus particles, also via an interaction with the C-terminus of Gag.^{390,818}

Interestingly, in the HIV-2/SIV_{sm}/SIV_{mac} lineage, two of the major functions of HIV-1 Vpr seem to be divided between Vpx and Vpr: Vpx is required for efficient infection of nondividing cells,⁸⁴⁰ whereas Vpr induces cell cycle arrest but has no role in nuclear targeting.²²³

The ability of Vpx to promote infection of nondividing cells (e.g., monocyte-derived macrophages and dendritic cells) is thought to result not from its karyophilic properties but rather from its ability to counteract a host cell restriction factor that blocks reverse transcription in these cell types. Vpx can elicit this function *in trans*; treating macrophages or dendritic cells with Vpx-containing virions can suppress the block to subsequent infection by Vpx-deleted SIV_{sm} or HIV-2.²⁷⁶ Likewise, as mentioned earlier, HIV-1 is known to infect dendritic cells and monocytes inefficiently. Again, this block can be reversed by prior treatment with Vpx-containing SIV_{mac}.^{276,382,486} The ability of Vpx to promote infection of dendritic cells and macrophages *in trans* extends to viruses as divergent as MLV.³⁸² This Vpx activity involves engagement of the DCAF1/DDB1/CUL4 E3 ubiquitin ligase complex discussed earlier in the context of Vpr activity.^{690,716}

It was recently reported by several groups^{46,328,418} that SAMHD1 is a strong candidate for the host factor in myeloid cells (e.g., macrophages and dendritic cells) that is counteracted by Vpx. SAMHD1 is an interferon-induced protein that is defective in some patients with Aicardi-Goutières syndrome, an autoimmune disorder that resembles congenital viral infection and is associated with inflammation and impaired breakdown of cytosolic nucleic acids.⁶²⁵ Vpx delivered into the monocytic cell line THP-1 bound SAMHD1⁴¹⁸ and SAMHD1 was recovered in association with both Vpx and with Vpx-DCAF1/DDB1/CUL4 complexes in 293T cells but not with DCAF1/DDB1/CUL4 complexes lacking Vpx.³²⁸ Delivery of WT Vpx into primary macrophages or THP-1 cells induced the degradation of SAMHD1.^{328,418} Importantly, a Vpx mutant unable to associate with the DCAF1/DDB1/CUL4 complex did not promote SAMHD1 degradation and SAMHD1-mediated degradation was blocked by proteasomal inhibitors, consistent with Vpx serving as an adaptor to target SAMHD1 for proteasomal degradation via the DCAF1/DDB1/CUL4 complex. SAMHD1 depletion in primary MDMs and MDDCs enhanced infection by single-cycle reporter virus by increasing viral cDNA synthesis.^{46,328,418} PBMCs from patients with Aicardi-Goutières syndrome are highly susceptible to a spreading HIV-1 infection even in the absence of activation.⁴⁶

Further studies will be required to decipher the mechanism by which SAMHD1 blocks efficient reverse transcription in myeloid cells. It may be relevant that Aicardi-Goutières syndrome is associated not only with mutations in SAMHD1 but also with defective alleles for two nucleases—TREX1 and RNase H2.¹⁵³ Thus, SAMHD1 may function in regulating levels of cytosolic nucleic acids and as a consequence of this activity may reduce levels of incoming viral DNA. Alternatively, SAMHD1 has been shown to possess deoxyguanosine triphosphate (dGTP)-regulated deoxynucleotide triphosphohydrolase activity,^{267,615} leading to the suggestion that this protein might reduce dNTP pools in cells in which it is highly expressed (e.g., dendritic cells), thus limiting the efficiency of reverse transcription early postinfection.

It has been reported that the inability of HIV-1 to infect immature dendritic cells, likely a consequence of SAMHD1

expression, prevents the activation of antiviral innate immunity. Bypassing the block to HIV-1 infection in this cell type with Vpx stimulates HIV-1 infection, leading to dendritic cell maturation and induction of an antiviral type 1 interferon response.⁴⁸⁶ This response requires *de novo* synthesis of Gag and induction of the transcription factor interferon regulatory factor 3 (IRF3). The fact that HIV-1 does not trigger this dendritic cell-mediated innate antiviral response may contribute to the inability of humans to exert long-term immunologic control of HIV-1 replication.⁴⁸⁶ Thus, the absence of a *vpx* gene in HIV-1 may contribute to HIV-1 pathogenesis.

Vpu

A distinguishing feature of the HIV-1 lineage of primate lentiviruses is the presence of the *vpu* gene (see Fig. 49.6); it is absent from HIV-2 and from nearly all SIVs examined to date. Vpu is a multimeric, 81-amino acid, integral membrane phosphoprotein containing an N-terminal transmembrane anchor sequence and an approximately 50-amino acid cytoplasmic domain. Three α -helical domains have been predicted: one in the transmembrane sequence (residues 6 to 29), the others in the cytoplasmic domain (residues 32 to 51 and 57 to 72).⁸¹⁴ The sites of phosphorylation have been mapped to two Ser residues at positions 52 and 56.⁶⁸⁰ Vpu is translated from a *vpu-env* bicistronic mRNA and is synthesized at intracellular levels comparable to those of Gag in virus-infected cells. Vpu has not been detected in virus particles. Two principal functions for Vpu have been described: enhancement of virus release and degradation of CD4.

Early studies observed that HIV-1 clones lacking a functional *vpu* gene displayed a pronounced defect in virus particle production.^{681,725,726,749} The absence of Vpu had no discernible effect on the processing or transport of Gag proteins but caused apparently mature, fully budded virus particles to be retained at the plasma membrane and in intracellular vesicles.³⁹⁹ It is important to note that the Vpu-minus particle release defect is distinct from that induced by late-domain mutation; in the former case, the virions have completed the budding and maturation process but remain tethered to the cell surface; in the latter case, the particles fail to undergo membrane fission and remain morphologically immature (see Fig. 49.33). Until 2008, the mechanism by which Vpu enhances particle release remained poorly understood, though it was noted that the ability of Vpu to promote virus release is cell type dependent. Its effect on virus release is observed in so-called Vpu-restrictive cells, which include some human T-cell lines, primary CD4⁺ T lymphocytes and MDMs, and epithelial cell lines like HeLa. In contrast, particle production in Vpu-permissive cells like 293T and in simian cell lines such as COS and CV-1 occurs efficiently even in the absence of Vpu. The observation that human-simian cell heterokaryons behave like the parental simian cells led to the hypothesis that Vpu overcomes a cellular inhibitor of virus release that is expressed in some human cells.⁷⁷² It was also observed that Vpu can increase virus production of highly divergent retroviruses (e.g., MLV, visna, and HIV-2), even though these viruses do not carry a *vpu* gene,²⁷⁴ and that interferon treatment can convert a Vpu-permissive cell type to one that is Vpu restrictive.⁵⁵⁷

In 2008, two groups independently reported that the host cell factor counteracted by Vpu is an interferon-inducible protein known as CD317 or BST-2 (bone marrow stromal cell

antigen 2) and subsequently renamed tetherin.^{558,765} Vpu-permissive cells were shown to express low levels of tetherin, whereas Vpu-restrictive cells expressed high levels. Ectopic expression of tetherin in Vpu-permissive cells was demonstrated to block the release of Vpu(–) but not that of Vpu(+) HIV-1. Conversely, siRNA-mediated depletion of tetherin from Vpu-restrictive cells converted these cells to a Vpu-permissive phenotype.

Tetherin is proposed to have an unusual topology in the plasma membrane, with an N-terminal cytoplasmic domain, a transmembrane region, an extracellular coiled-coil motif, and a C-terminal glycosyl phosphatidylinositol (GPI) anchor that directs tetherin localization to lipid rafts⁴¹³ (Fig. 49.36). The extracellular domain of tetherin is glycosylated and includes three Cys residues that are involved in intermolecular disulfide cross-linking.⁵⁶⁹ X-ray crystallography studies demonstrate that the tetherin ectodomain forms an extended dimeric coiled-coil.^{679,827} Tetherin proteins from nonhuman species (e.g., rodents and nonhuman primates) retain the ability to restrict HIV-1 release but cannot be counteracted by Vpu. The key coding differences that differentiate human from nonhuman tetherins in terms of their ability to be counteracted by Vpu map primarily to the transmembrane domain, and it has been demonstrated that the transmembrane domain of human tetherin interacts directly with Vpu.^{350,638} Remarkably, an artificial tetherin composed of foreign transmembrane, external coiled-coil, and GPI anchor domains retains the ability to restrict

HIV-1 release. As expected, this artificial tetherin cannot be counteracted by Vpu.⁵⁹⁴

The mechanism by which Vpu counteracts human tetherin to stimulate virus release has not been fully elucidated. It is clear that under some circumstances Vpu expression induces tetherin removal from the cell surface and its degradation by proteasomal and/or lysosomal pathways. However, under other conditions, Vpu can disrupt the ability of tetherin to retain HIV-1 particles on the cell surface without inducing any apparent reduction in tetherin levels. Furthermore, a tetherin mutant that is refractory to Vpu-mediated degradation can still be counteracted by Vpu.^{264,526,781} These observations indicate that Vpu may counteract the antiviral activity of tetherin by removing it from the site of budding without necessarily inducing its degradation. Recent data suggest that Vpu does not alter the rate of tetherin internalization but diminishes its recycling, inhibits its transport to the cell surface, and traps it in the *trans*-Golgi network.⁶⁷⁴

As mentioned previously, early studies observed that Vpu is able to stimulate the release of retroviruses that are distantly related to HIV-1 (e.g., the gammaretrovirus MLV),²⁷⁴ suggesting that tetherin may possess a broad ability to restrict virus release. Indeed, tetherin has been shown to tether diverse enveloped viruses to the cell surface; these include many genera of *Retroviridae* (e.g., HIV-2, HTLV-1, MLV, EIAV, FIV, M-PMV, PFV) and nonretroviral enveloped viruses (e.g., filoviruses, arenaviruses, herpesviruses).^{193,368,653} Several of these viruses have, in turn, evolved mechanisms to counteract

FIGURE 49.36. Hypothetical models for the tethering of human immunodeficiency virus 1 (HIV-1) virions to the cell surface by tetherin (CD317/BST-2). The tethered virion is at the **top**, with matrix (MA) in green and the capsid core in black. Tetherin is shown on the **left** anchored in the lipid bilayer of the plasma membrane, with the cytoplasmic tail (CT), transmembrane (TM), and coiled-coil (CC) domains and the putative glycosyl phosphatidylinositol (GPI) anchor indicated, with the CC domain highlighted in red. In model **(i)**, two molecules of tetherin are oriented in parallel, with the TM domains embedded in the plasma membrane and the GPI anchors in the viral membrane. In model **(ii)**, one molecule is embedded in the viral membrane, the other in the plasma membrane, with the two molecules associating via their CC domains. (Adapted from Adamson CS, Freed EO. Novel approaches to inhibiting HIV-1 replication. *Antiviral Res* 2010;85:119–141.)

tetherin restriction (for review see¹⁹³). As detailed earlier, HIV-1 uses Vpu to neutralize tetherin. Some strains of HIV-2 and SIV have evolved a mechanism whereby the Env glycoprotein induces the sequestration of tetherin in an intracellular, perinuclear compartment.²⁸⁷ The glycoprotein of Ebola virus (a filovirus) has also been reported to possess antitetherin activity.³⁷³ A number of SIVs use Nef to antagonize tetherin.^{360,848} The ability of SIV Nef to counteract tetherin is primate species specific, with critical determinants for Nef antitetherin activity mapping to the N-terminal, cytoplasmic domain of tetherin. Kaposi's sarcoma-associated herpes virus (KSHV) encodes a protein known as K5—a RING finger family ubiquitin ligase—that induces the ubiquitylation of a Lys residue in the cytoplasmic domain of tetherin and, consequently, its ESCRT-dependent lysosomal degradation.^{492,582} It is clear from the diverse strategies that enveloped viruses have evolved to counteract tetherin that this protein represents a potent and broadly acting component of the host innate immune response. Although tetherin clearly restricts the release of enveloped viruses, the role of tetherin in cell–cell viral transfer remains to be defined. Some studies have reported that tetherin restricts cell–cell HIV-1 transfer,^{108,411} whereas others concluded that tetherin actually promotes cell–cell transmission.³⁶⁴ Considering the central role of cell–cell transfer in retroviral biology, this will be an important issue to resolve.

Sequence analysis of tetherin coding regions from across a number of primate species has revealed that this gene is undergoing rapid positive selection, likely in response to lentiviral infections.⁵¹⁴ Most notably, a motif in the cytoplasmic domain of tetherin that is required for Nef's antitetherin activity is deleted in humans,⁴⁵³ rendering human tetherin resistant to antagonism by HIV-1 Nef. As discussed earlier in this chapter, HIV-1 infection in humans is thought to have originated from cross-species chimpanzee-to-human transmission of SIV_{cpz}.²⁵² Although SIV_{cpz} does encode Vpu, the SIV_{cpz} protein does not possess antitetherin activity.⁶⁶³ It therefore appears that Vpu acquired the ability to counteract tetherin after transmission of SIV_{cpz} from chimpanzees to humans.

The second main function of Vpu—CD4 degradation—has been characterized in some detail. Vpu binds directly to the cytoplasmic tail of CD4 in the ER; residues in the cytoplasmic domain of Vpu, and Vpu phosphorylation, are critical for this process. Recent findings support a model whereby Vpu mediates the degradation of CD4 by two distinct mechanisms: retention in the ER and degradation by an ER-associated degradation (ERAD)-like pathway.⁴⁷⁸ Vpu simultaneously interacts with CD4 and the human β -transducin repeat-containing protein (h- β TrCP) subunit of the SCF (Skp–Cullin 1–F-box) ubiquitin ligase complex. CD4 is then targeted for ubiquitin-mediated proteasomal degradation.⁴⁹³ The degradation of CD4 by Vpu liberates the Env glycoprotein precursor gp160 from its interaction with CD4, thereby enabling Env to continue its transport to the cell surface.⁸⁰³

In addition to counteracting tetherin and inducing the degradation of CD4, Vpu has also been reported to down-regulate CD1d and the NTB-A receptor from the cell surface.^{530,688}

Nef

The *nef* gene, present only in primate lentiviruses, overlaps approximately one-half of the 3' LTR (see Fig. 49.6) and encodes a ~25- to 34-kD membrane-associated phosphoprotein that is incorporated into virions and associates with

the viral core. Membrane binding, mediated by a covalently attached myristic acid moiety and a cluster of N-terminal basic residues,⁷⁹⁶ is critical for most Nef functions. Nef is synthesized at high levels from the first multiply spliced mRNA transcript detected postinfection. Although Nef was originally labeled a “negative factor” because of reports that it down-regulated virus replication by suppressing transcription from the HIV LTR, it is now clear that in cultured cells Nef expression either has no effect on virus spread or modestly enhances replication kinetics. Positive effects of Nef on virus replication in culture are most pronounced when target cells are not highly activated. *In vivo*, Nef appears to be a key contributor to sustained lentiviral replication and pathogenesis.

Nef is composed of several structural domains: an N-terminal “anchor” domain, a “core” domain, and a flexible C-terminal domain. The NMR structure of the core domain was determined in the mid-1990s,^{284,285} and x-ray crystal or NMR structures of the core domain were solved for the protein in a complex with Src homology 3 (SH3) domains^{23,431} or with the cytoplasmic tail of CD4.²⁸⁶ The Nef core contains an acidic cluster, a polyproline domain, and a dileucine motif important for the protein's interactions with cellular factors. Recently the structure of full-length Nef in a complex with the regulatory domain of the Src-family kinase Hck was solved by NMR.³⁷²

Deletion of the *nef* gene has a profound effect in the SIV/rhesus macaque animal model. Monkeys inoculated with *nef*-deleted mutants develop high-level antibody responses and are unable to sustain the SIV infection *in vivo*³⁸⁹; these results indicate that Nef plays a critical role in initiating and sustaining SIV infection *in vivo*. Nef has also been proposed to play a major role in pathogenesis in HIV-1-infected humans. This hypothesis stems in part from the findings of studies that show that patients infected with virus isolates harboring Nef mutations progress to disease very slowly.^{175,398} Nef-minus SIV has been used as an attenuated vaccine in the macaque model.¹⁵⁸ Nef potentiation of lentiviral replication *in vivo* is thought to result primarily from its ability to activate T cells and facilitate immune evasion.²⁰ However, because of its pleiotropic properties and multitude of interaction partners, the role of Nef in HIV/SIV pathogenesis remains incompletely understood.

A number of functions for HIV-1 and SIV Nef have been reported: (a) down-regulation of a wide array of cell surface molecules, including CD4, MHC-I, CD8, the CD3 T-cell receptor complex, and the co-stimulatory molecule CD28; (b) enhancement of virus infectivity; and (c) modulation of cellular activation and signaling pathways. Many of these functions appear to be linked to a generalized disruption of endosomal trafficking induced by Nef. The contribution of these diverse activities to the role of Nef in maintaining high viral loads *in vivo* remains to be fully understood.

Like the HIV-1 Env and Vpu proteins, Nef down-regulates cell surface expression of CD4. Nef-induced CD4 down-regulation proceeds in a step-wise fashion: (a) Nef interacts with the cytoplasmic domain of CD4⁹ and then associates with the clathrin adaptor protein complex AP-2 in clathrin-coated pits; this ternary CD4–Nef–AP-2 complex is then internalized.^{116,455} (b) Nef induces the ESCRT-dependent sorting of internalized CD4 to the MVB and, ultimately, to the lysosome for degradation.¹⁶⁴ Alternatively, it has been reported that in the endosome, Nef connects CD4 with the β -subunit of COPI coatomers (β -COP), thereby targeting CD4 for degradation in the

lysosome.^{41,600,668} In either case, Nef induces both CD4 internalization from the cell surface and sorting to the lysosome. CD4 down-regulation by Nef helps limit superinfection and may mitigate inhibitory effects of high CD4 expression on virus release and Env incorporation.^{420,643}

In addition to reducing cell surface levels of CD4, Nef down-regulates the expression of MHC-I and other surface molecules.⁶⁸⁴ The mechanism by which Nef down-regulates MHC-I is distinct from that used to reduce CD4 expression and is less well understood. Nef-induced MHC-I down-regulation reportedly involves the formation of a Nef-MHC-I complex and AP-1-dependent redirection of MHC-I from the *trans*-Golgi network to lysosomes.^{278,377,428,565,635} Redirection of MHC-I to the lysosome by Nef may also involve β -COP, but it has been suggested that Nef uses a different binding site on β -COP for MHC-I down-regulation than used for CD4 degradation.^{439,668} Some evidence supports an alternative model whereby Nef reduces surface expression of MHC-I by stimulating its internalization from the plasma membrane via an ARF6-dependent pathway.⁶⁶ MHC-I down-regulation blocks proper antigen presentation—thereby limiting the ability of cytotoxic T lymphocytes to recognize and eliminate virus-infected cells—thus providing HIV and SIV with a mechanism for partially evading at least one component of the host immune response.^{147,443,735} Removing MHC-I molecules from the cell surface exposes infected cells to attack by NK cells; HIV-1 may avoid this latter problem by not down-regulating those class I molecules (human leukocyte antigen-C [HLA-C] and HLA-E) responsible for protection from NK cell lysis.¹⁴⁵ Nef also down-regulates surface expression of CD3 and CD28, among others,^{39,736} but the mechanisms responsible for this down-regulation are less well understood than for CD4 and MHC-I. As alluded to earlier, in many cases the modulation of surface protein expression by Nef relies on its ability to serve as an adaptor between these proteins and cellular AP complexes.

In single-cycle assays, Nef modestly stimulates virus infectivity.^{130,266,524,715} This function appears to be manifested at an early postentry step in the virus life cycle, because *nef*-deleted mutants display no defect in virion-cell fusion⁷⁵⁴ yet fail to efficiently reverse transcribe their genomes after entry.^{10,129,683} At this time, the mechanism by which Nef enhances virus infectivity remains to be elucidated. Interestingly, the infectivity defect observed with *nef*⁻ virus can be partially suppressed by pseudotyping with VSV-G.⁸ The role Nef plays early postentry is therefore influenced by the route of virus entry, because VSV-G directs entry via fusion in a low-pH endosome after endocytosis, whereas HIV-1 Env is thought to primarily mediate entry via direct fusion at the plasma membrane. It has been reported that Nef stimulates cholesterol biosynthesis and increases cholesterol and ganglioside transport to rafts and virions,^{855,856} perhaps in some cell types by impairing cholesterol efflux mediated by the adenosine triphosphate (ATP)-binding cassette transporter A1 (ABCA1).⁵⁴⁴ The resulting Nef-mediated increase in virion cholesterol could promote virus infection; however, this remains to be demonstrated and the relevance of these observations is unclear.^{214,708} Because Nef is a core-associated protein, it may modulate uncoating or regulate trafficking of the core early postentry, perhaps by enhancing the ability of the incoming core to penetrate the cortical actin network located beneath the plasma membrane.⁹⁹ Interestingly, HIV-1 Nef interacts with dynamin 2, and transfection

of dominant-negative dynamin 2, or dynamin 2 siRNA, in the virus-producing cell blocks the ability of Nef to enhance particle infectivity.⁶⁰² The mechanistic basis for these observations remains to be understood.

A number of studies have shown that HIV and SIV Nef influence cellular signal transduction pathways and affect the activation state of Nef-expressing cells (for review see²²⁵). The effect of Nef in potentiating T-cell activation is due in part to its interaction with the cellular Ser/Thr kinase p21-activated kinase 2 (PAK2). This interaction reportedly occurs in lipid rafts and results in the recruitment of Nef to the immunologic synapse.^{214,408} The co-localization of Nef and PAK2 at the immunologic synapse may play an important role in up-regulating the expression of the transcription factor NFAT (for nuclear factor of activated T cell),²¹⁴ which in turn leads to T-cell activation, as described earlier in the LTR section. Indeed, Nef has been reported to induce expression of a number of genes whose products positively regulate HIV replication.⁷⁰¹ Another reported consequence of the Nef-PAK2 interaction is the phosphorylation-dependent inactivation of cofilin, an actin-depolymerizing factor. Inactivation of cofilin by this route inhibits T-cell chemotaxis and motility, potentially enhancing immune evasion of HIV-1-infected cells.⁷²¹

As mentioned earlier, HIV and SIV Nef contain a highly conserved consensus binding site for the SH3 domain of Src-family Tyr kinases (Pro-X-X-Pro). Nef has been reported to bind several of these kinases (e.g., Lyn, Hck, and Lck) and modulate their catalytic activities. Because cellular kinases are intimately involved in signaling pathways, such interactions may play a critical role in Nef function. In addition to direct effects of Nef on stimulating T-cell activation, Nef expression in macrophages reportedly induces the expression and release of the β -chemokines MIP-1 α and MIP-1 β , which in turn activate resting T lymphocytes.⁷³⁸ Furthermore, Nef-expressing macrophages release factors that act on B cells to increase the sensitivity of resting T lymphocytes to HIV-1 infection.⁷³⁷ Such paracrine pathways could help explain the positive effect of Nef on HIV-1 replication *in vivo*. Nef expression also triggers the release of exosomes that contain factors including Nef itself; it has been suggested that this Nef-induced exocytosis may play an important role in Nef function.^{37,436,548}

Although it is well established that Nef is crucial to HIV and SIV pathogenesis, it remains to be determined which of the many functions attributed to Nef in culture are required for its ability to potentiate efficient replication and disease progression *in vivo*. Studies have been performed with SIV Nef mutants in an attempt to define which activities of Nef are required for the maintenance of high viral loads in infected animals. Results of these studies have suggested that mutations that interfere with the ability of Nef to down-regulate CD4, MHC-I, CD3, and CD28 attenuate virus replication *in vivo*.^{343,545,672} Mutations that disrupt the ability of Nef to enhance virus infectivity *in vitro* are also detrimental to virus replication in monkeys.³⁴³ Results are less clear for Nef-mediated activation of PAK2. This function of Nef either may not be required *in vivo* or may be required only late in disease progression.^{343,664} Attempts to establish the *in vivo* significance of the many reported activities of HIV-1 Nef are complicated by the fact that individual mutations often disrupt multiple Nef activities and by differences in the functional determinants of HIV-1 versus SIV Nef. However, understanding the differences between the Nef proteins

from SIV (which are often nonpathogenic in the natural hosts) and HIV-1 (which is highly pathogenic) may provide important clues to Nef function. For example, it has been suggested that the ability of SIV but not HIV-1 to down-regulate CD3 may correlate with the different pathogenic outcomes of infection by these viruses.⁶⁷³

As discussed earlier in the section on Vpu, the Nef proteins of many SIVs possess the ability to antagonize the host restriction factor tetherin.^{360,663,848} The capacity of Nef to counteract tetherin involves the removal of the host protein from sites of budding on the plasma membrane and requires domains of Nef that interact with AP-2.⁸⁴⁷ Thus, tetherin represents yet another host cell factor that is down-regulated by Nef through interaction with cellular clathrin adapter protein complexes.

PERSPECTIVES

Despite its relatively recent emergence as a major human pathogen, HIV-1 has become one of the most intensively studied and best-understood viruses. As this chapter illustrates, an enormous amount of information has been obtained regarding the molecular, biochemical, biological, and structural details of all aspects of the HIV-1 replication cycle. Recent breakthroughs in our understanding of how lentiviruses parasitize host cell machinery to promote virus replication and, conversely, how the host cell has evolved to specifically restrict lentivirus infection have provided remarkable insights into the dynamic nature of this complex host–pathogen interaction. Although the wealth of information available on HIV-1 and related lentiviruses has led to the development of several classes of antiretroviral drugs that effectively suppress HIV-1 replication in infected patients, controlling the AIDS epidemic remains an elusive goal, particularly in developing nations. Future progress in HIV research will undoubtedly lead to more effective approaches for controlling HIV-1 and will continue to drive advances in virology, immunology, and cellular, molecular, and structural biology.

against a variety of normally innocuous agents that become the major sources of morbidity and mortality. Over the 30 years since the original identification of a new syndrome that was ultimately shown to be caused by HIV,⁵⁵ the infection has become a grave humanitarian crisis with far ranging impact on international political and economic stability, and contributes greatly to global health inequalities in terms of access to life-saving therapies.

EPIDEMIOLOGY

The initial clues to the emerging HIV epidemic came from two linked observations in 1980–1981. One was from front-line physicians, predominantly in New York and California, who were confronted with previously healthy young men presenting with symptoms of profound unexplained immune deficiency. The other was at the Centers for Disease Control and Prevention (CDC) in Atlanta, which noted a marked increase in the number of requests for pentamidine, a drug used to treat an infection associated with severe immunodeficiency. The link between these observations was the sudden upsurge in cases of *Pneumocystis jirovecii* (formerly *P. carinii*) pneumonia being diagnosed in young gay men, an opportunistic infection previously seen in the setting of immune suppression accompanying cancer chemotherapy, but now, for the first time, appearing in persons with no obvious disposition to develop immune deficiency.

By 1984, the viral etiology of what became known as HIV type 1 (HIV-1) infection had been confirmed through the isolation of a lymphotropic retrovirus from infected persons, and the detection of antibodies in persons at risk.^{22,127,322} It was clear that certain groups were particularly at risk, including gay men, injection drug users, recipients of blood transfusions, and hemophiliacs, and that the mechanisms of transmission began to be defined.^{81,189} By April 1985, a blood test for detection of antibodies was licensed, and the extent of the epidemic began to unfold. Since the initial detection of the epidemic in the United States and Europe, it has grown to involve an estimated 60 million persons worldwide, with 5 million new infections per year, with epidemics expanding in eastern Europe, south Asia, and China³¹⁷ (Fig. 50.1). In Southern Africa, less than 1% of the population was infected in 1990, when large scale surveillance programs were initiated, whereas by 2004 antenatal screening surveys detected a prevalence well in excess of 30% in some areas.³⁰⁸

Origin of HIV

The global epidemic of HIV-1 is the result of a cross-species infection of humans by a chimpanzee lentivirus, simian

Human immunodeficiency virus (HIV) is essentially an infection of the immune system. The main clinical manifestation of infection is the progressive and ultimately profound defect in cell-mediated immune responses that are essential for protection

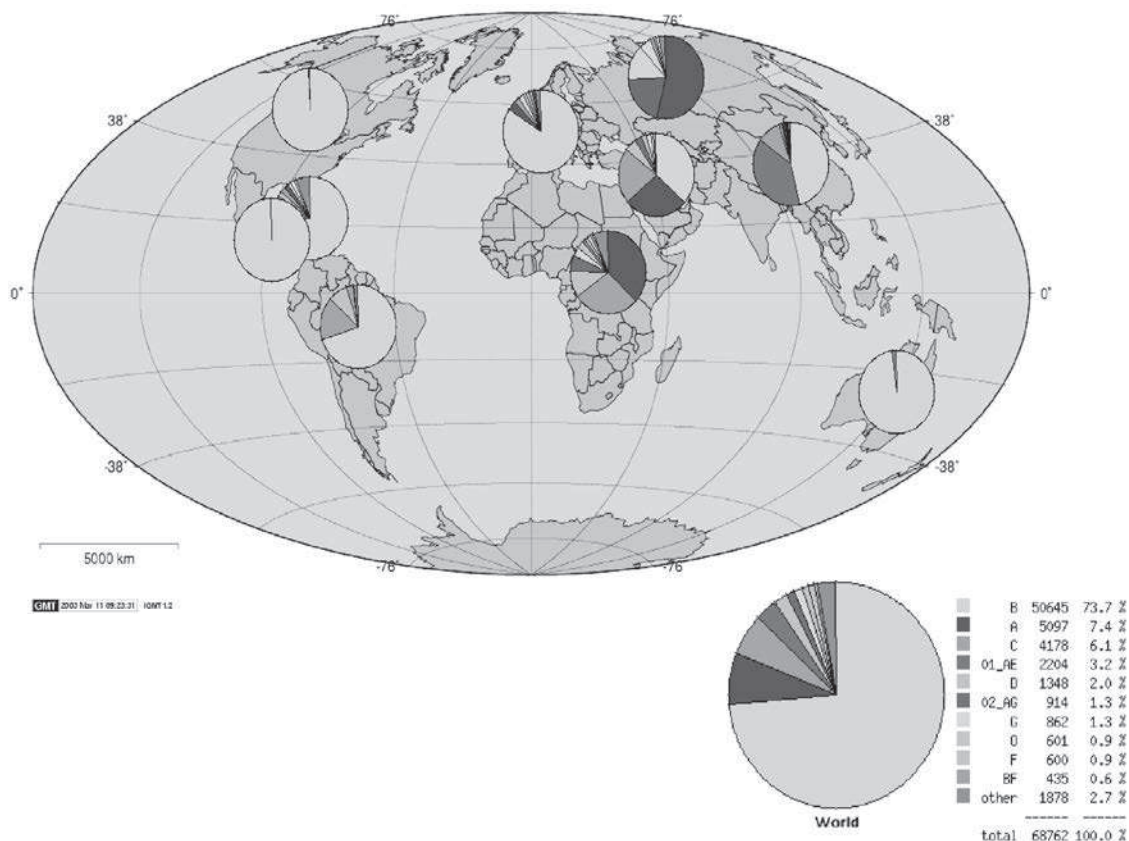

FIGURE 50.1. Global subtype distribution of human immunodeficiency virus type 1 (HIV-1) clades as reported in the Los Alamos Database.

immunodeficiency virus (SIV_{cpz}), which occurred in west central Africa.¹³¹ Chimpanzees, in turn, appear to have acquired SIV_{cpz} sometime after their divergence into multiple subspecies. *Pan troglodytes* and *P.t. schweinfurthii* are naturally infected, whereas other closely related species are not, suggesting that SIV_{cpz} is unlikely to have coevolved with its natural host.³⁶⁶ How the virus initially arose as a new virus in chimpanzees remains unclear, but it likely occurred following transmission of two other ancestral SIV species from monkeys,³⁶⁶ perhaps because chimpanzees hunt monkeys for food. Of note, SIV_{cpz} is not an asymptomatic infection in chimpanzees; the epidemiologic evidence documents decreased survival in chimpanzee troops infected by SIV_{cpz}.²⁰⁹ In contrast, other SIV infections appear to be largely asymptomatic in their natural monkey hosts (i.e., SIV_{smm} in sooty mangabeys) and do not lead to immune deficiency or decreased life span. Experimental transmission of these viruses to susceptible non-natural hosts can result in progressive and profound immunodeficiency and acquired immunodeficiency disease (AIDS).³⁵⁴ In fact, the transmission of SIV_{smm} in West Africa is the origin of the HIV-2 epidemic in humans.³⁵⁴ Although the reasons for differences in transmissibility and pathogenicity during cross-species transmission are not fully understood, it is clear that innate host defenses such as those imparted by apolipoprotein B messenger RNA (mRNA)-editing enzyme, catalytic polypeptide-like 3G (APOBEC3G), and tripartite motif 5 alpha (TRIM-5α) play a role and create barriers that viruses must overcome in order to

become established and survive within a new host species (see Chapter 49).

At least three distinct cross-species transmissions from chimpanzees to humans are thought to have occurred, giving rise to three highly divergent genetic lineages of infection, termed groups M, N, and O.^{158,302,372} Group M is by far the most widespread, accounting for most cases globally. Because the greatest genetic diversity in group M is found in Kinshasa, Zaire, the epidemic likely began in this region of Africa. The approximate date of introduction of the M group into the human population is estimated to be around 1931, based on supercomputer analysis of large numbers of sequenced HIV isolates, assuming a constant rate of evolution.²¹⁸ This approach has been validated by successfully timing the earliest historic isolate, which was sequenced from a stored plasma sample obtained in 1959 from a person who died of AIDS in Manchester, England.⁷⁷

Current Global Distribution

The most heavily affected continent at the present time is Africa, with an estimated 25 million persons currently infected with HIV, and at least 3 million with advanced disease in need of treatment. HIV infections have increased markedly over the last decade, despite knowledge of the mechanisms of transmission. Expanding epidemics in Eastern Europe, South Asia, and China may ultimately eclipse the African epidemic in terms of sheer numbers of infected persons. The viruses fueling these epidemics vary according to geographic region, with clade C

TABLE 50.1 Risk of Transmission of HIV-1**Sexual transmission**

Female-to-male transmission.....	1 in 700 to 1 in 3,000
Male-to-female transmission.....	1 in 200 to 1 in 2,000
Male-to-male transmission.....	1 in 10 to 1 in 1,600

virus being the most prevalent worldwide and clade B being currently the most prevalent in the United States and Europe. Clades differ one from another by up to 35%; within a single clade variation between isolates can be as great as 20%. Mistakes in reverse transcription, which occur because the viral reverse transcriptase lacks an editing function, leads to variability of individual virus sequences within a single infected person that can exceed what is seen with other viruses (e.g., influenza) over the course of a global epidemic.¹³⁵

Mechanisms of Transmission

Most cases of HIV infection worldwide are the result of sexual transmission, but important modes of transmission also include parenteral transmission and transmission from mother to infant. The actual risk of transmission per exposure varies widely (Table 50.1). For sexual transmission, the risk of male to male transmission is greater than the risk of heterosexual transmission, and is highest in persons practicing receptive anal intercourse.³⁴⁸ Overall, the greatest risk of transmission is from contaminated blood transfusions, with 95 of 100 persons becoming infected, although transfusion-related infections are rare now that blood is routinely screened for this pathogen.³⁶¹ The rate of transmission depends on the inoculum size delivered, but perhaps also on local mucosal defense mechanisms that modulate infection but remain to be defined. Population studies performed in Africa suggest that there is a threshold viral load (~1,500 RNA copies/mL plasma) below which the likelihood of sexual transmission is greatly reduced.^{150,325}

Mathematical modeling suggests that the published risks of sexual transmission, which come from longitudinal studies of persons in identified risk groups, are too low to account for the huge numbers of infections worldwide and for the rapid increase in infections that occur after puberty. In South Africa, for example, 4% of 16-year-old girls are HIV seropositive, whereas by age 21 this number increases to 31%.³⁰⁸ Coital frequency estimates in these same age groups fail to account for this rapid increase in infections. More recent data suggest that transmission is amplified during periods of increased genital tract viral shedding.¹²⁸ Increased shedding certainly occurs at the time of

acute infection, which has been shown through a study of more than 15,000 persons in 56 villages in Uganda to be a particularly important period for transmission and, thus, has important public health implications.⁴¹¹ An important aspect of this study was that it followed couples who were both seronegative at the time of enrollment, so it was not potentially selecting for discordant couples who might have already demonstrated some intrinsic resistance to transmission. Other factors that may amplify the risk of transmission include other co-infections (e.g., malaria and tuberculosis, sexually transmitted diseases [STDs], or in particular co-transmission of STD and HIV).⁷¹ Estimated transmission probability likely also depends on genetic factors, such as density of the HIV co-receptor CCR5 on cervical cells.⁵⁸ In addition to using epidemiologic data, much has been learned about transmission across a mucosal barrier by studying the SIV system, where it has been shown that CD4 T cells are the first cells to be infected (as opposed to antigen-presenting cells), and that there is a small temporal window of opportunity in which antiviral therapy or immune responses can block viral dissemination.^{159,433}

PATHOGENESIS

Human immunodeficiency virus directly infects and kills cells that are critical for effective immune responses. Through direct interaction between the viral envelope and its cellular receptor, CD4 and the chemokine coreceptor, CCR5 or CXCR4 (see Chapter 49), this virus infects key cells of the adaptive immune response, explaining the clinical manifestations of disease being profound immune suppression. The course of disease varies enormously among infected persons. The time from acute infection to the development of AIDS, defined by a CD4 cell count of less than 200 cells/ μ L or the appearance of AIDS-defining opportunistic infections or cancers, can be as rapid as 6 months.³¹⁰ Other persons have been known to be infected for more than 25 years and to maintain normal CD4 cell levels and exhibit no evidence of CD4-cell decline or immune deficiency, despite never having been treated with anti-HIV medications.²⁷¹ A precise explanation for these differences in disease development remains elusive, but increasing evidence suggests that early events at the time of acute infection, together with viral and host genetics, play a determining role in the clinical outcome of disease.

Acute Infection and CD4 Cell Depletion

Ever since the analysis of viral load in the Multicenter AIDS Cohort Study (MACS) dataset in 1996,²⁶⁷ it has been clear that the course of HIV infection can be predicted within the first 6 to 12 months based on plasma viral load, and that CD4 count at this time also independently helps to determine whose disease will progress rapidly and whose will not.²⁴⁶ The median viral load in plasma at the time of peak viremia during acute infection is approximately 10^6 to 10^7 RNA copies/mL, which drops to a mean set point of 30,000 copies/mL within the first 6 to 12 months of infection. Longitudinal studies from the MACS, which were initiated before the availability of effective antiviral therapy, revealed the interquartile ranges of viral load and the relationship to risk of disease progression (Fig. 50.2). Interestingly, at 1 year after infection, only a fivefold difference

FIGURE 50.2. Interquartile ranges of viral load within one year of acute human immunodeficiency virus (HIV) infection. (Adapted from Lyles RH, Munoz A, Yamashita TE, et al. Natural history of human immunodeficiency virus type 1 viremia after seroconversion and proximal to AIDS in a large cohort of homosexual men. *J Infect Dis* 2000;181:872–880.)

was seen in plasma viremia between the quartile that does the best and the quartile that does the worst.²⁴⁶

Studies in both humans infected with HIV^{43,264} and the SIV macaque model^{1234,261} provide important new insights into why the period of acute infection plays such a defining role in ultimate disease progression, and why the immune system ultimately fails to control HIV in most infected persons. Infection and depletion of large numbers of both resting and activated memory CD4 cells in the gut during primary infection may be what fuels the initial peak viremia, and likely places constraints on subsequent adaptive responses^{43,264} (Fig. 50.3). Details of what is happening at a cellular level in acute infection have come from experimental infection of macaques with SIV. At the time of acute SIV infection, massive infection occurs of gut-associated lymphoid tissue, with between 30% and 60% of all gut-associated CD4 cells becoming productively infected, leading to massive depletion of these cells in only 4 days.²⁶¹ The memory cell population, including both activated and resting memory cells, seems most vulnerable.²³⁴ In the earliest stages of infection, more than half of all memory CD4+ T cells are lost, and the body is left to fight the prolonged chronic phase of infection with a severely constricted repertoire of CD4 T helper cells. These experiments in the SIV model are almost certainly representative of what is happening in acute HIV infection in humans, where the initial plasma viral load averages 1 to 10 million RNA copies/mL. Whether the subsequent decline to a steady state results from active inhibition by innate and adaptive immune responses to HIV, or a decrease in the number of cells available to support viral replication, remains an area of dispute.³¹²

Most of the CD4 T cells that are depleted from the gut during acute HIV or SIV infection are T helper cells that produce interleukin 17 (IL-17) (Th17 cells). These cells are crucial for maintaining the integrity of the mucosal barrier, and their depletion by HIV or SIV leads to loss of epithelial integrity within the gut mucosa, thereby allowing translocation of gut-associated microbial products into the systemic circulation.¹¹⁰ These products are a major driver of the systemic immune activation that is a predominant feature of all pathogenic HIV and

SIV infections.^{41,42} The loss of CD4 T cells from the gut during acute infection therefore has two effects upon the immune system: it depletes a major portion of the immune reserve in the form of memory CD4 T cells, and it allows microbial translocation, which establishes a state of chronic immune activation that further promotes systemic HIV infection and replication.

Establishment of a Latent Viral Reservoir

During the period of acute infection, a stable reservoir of HIV-infected resting memory CD4 cells is established that harbors replication-competent, integrated provirus.^{63,116} This occurs whether or not persons are started on treatment in the initial symptomatic stage of infection. Because proviruses that form this latent reservoir are not transcriptionally active, no viral proteins or enzymes are produced. These infected cells therefore are protected from the effects of antiviral drug therapy and from immune attack. This latent reservoir is present whether the viral load is high or low, and it persists even after prolonged highly active antiviral therapy.¹¹⁵ A rough estimate is that about 1 in 1×10^6 CD4 cells harbors integrated latent provirus.⁴³⁴ The half-life of infected cells is such that it would take more than 70 years to achieve viral eradication by gradual senescence of these cells even with no blips in viremia on therapy,⁴³⁴ a situation that is yet to be achieved (see below).

HOST IMMUNITY

Recovery from many human viral infections is not associated with the eradication of infection, but rather results from immune-mediated containment. For example, persons who develop herpes zoster caused by varicella zoster virus infection ultimately contain the initial infection with a potent immune response.⁹² The virus remains present for the rest of the life of the infected individual; in most persons, however, it is controlled by an effective immune response. Although HIV infection is associated with progressive and ultimately profound immune suppression, a highly variable course of disease is seen among infected persons. After more than 25 years since the humoral and cellular

FIGURE 50.3. Appearance of the terminal ileum in human immunodeficiency virus (HIV) infection. **A:** Uninfected. **B:** HIV infected, showing dramatic loss of lymphoid tissue. **C:** Uninfected, showing numerous CD4 T cells in the lamina propria by immuno-histochemical staining. **D:** HIV infected, showing depletion of CD4 T cells in the lamina propria.

immune responses to HIV were identified, multiple correlates of immune control have been defined, but which are the cause of a better outcome, and which are the effect, remains elusive. Currently, data support contributions to disease outcome from adaptive immune responses, innate immune responses, host genetic factors, and differences in viral pathogenicity.

Innate Immune Responses

The initial immune response to HIV involves innate immune mechanisms. Toll-like receptors (TLRs) on dendritic cells (DCs) are activated by a combination of HIV-1 RNA via TLR7 and microbial products (discussed earlier) via other TLRs, resulting in high levels of interferon alpha ($\text{IFN-}\alpha$), IL-12, tumor necrosis factor alpha ($\text{TNF-}\alpha$), and IL-6, which together result in a profound activation of the immune system.^{23,42,169} These activated DCs can be infected with HIV, which may further contribute to impaired DC function in infected persons.^{245,355} Natural killer (NK) cells are also part of the initial innate immune response to HIV, and their numbers are greatly increased in acute infection. Because the increase in NK cells coincides with the initial decline in viremia after acute infection, these cells are thought to have a key role as an antiviral defense mechanism. Moreover, NK cells appear to be largely anergic in chronic infection, sug-

gesting that a pool of nonfunctional NK cells accumulates over time.⁷ The fact that expression of a killer cell inhibitory receptor, KIR3DS1, and a particular sequence in its ligand human leukocyte antigen (HLA) Bw4, is associated with slower disease progression²⁵⁷ also argues for an important role of these cells in infected persons.

Adaptive Humoral Immune Responses

HIV infection is associated with the development of antibodies that appear within weeks of initial infection. Although most of these antibodies bind, but do not neutralize,³¹⁹ a subset of these can neutralize virus, either by binding directly to the envelope glycoprotein trimer on the surface of free virions or following CD4-gp120 binding, preventing the fusion of the viral and cell membranes that is essential for viral entry.⁴⁷ The envelope is heavily glycosylated, and these sugars prevent antibody binding to the underlying peptidic structure. These neutralizing antibody responses nevertheless are sufficiently strong to influence viral evolution; indeed, the virus population *in vivo* is rapidly replaced by mutant virus that escapes recognition.^{339,412} This selection is an iterative process: new antibody responses develop to neutralize the mutant virus, which then escapes again. These responses are primarily narrowly directed

and do not appear to be able to broadly cross-neutralize many strains of HIV. During the chronic phase of infection, there is little evidence to indicate an ongoing contribution of neutralizing antibodies to immune control, as shown by depletion of antibody-generating B cells in an animal model of AIDS virus infection.³⁵⁷ Having said this, it is clear that sera from chronically infected individuals can potentially neutralize multiple strains of HIV broadly.^{27,99,235,382,409} Isolation of antibodies from these individuals has proven to be a rich source of monoclonal antibodies with broad and potent activity, and has led to the identification of potential targets of neutralizing antibodies for vaccine development.

Adaptive Cellular Immune Responses

CD8 T-Cell Responses

Adaptive immunity to viruses generally involves the rapid expansion of CD8 T cells that recognize viral proteins on the infected cell surface, presented by HLA antigen class I molecules. Recognition, via the T-cell receptor (TCR), of a foreign (nonself) protein presented as a short 8 to 10 amino acid peptide in the groove of a class I molecule can result in the directed lysis of that cell by CD8 T cells. Depending upon the kinetics of virus production, peptide presentation via class I, CD8 T-cell recognition, and the activation state of the CD8 T cell, virus-infected cells potentially can be eliminated before they are able to produce significant progeny virus.

In the early weeks following HIV infection, viral load is reduced from an average of 1×10^6 copies/mL to an average of 30,000 copies/mL.^{246,344} Coincident with this drop is the appearance of HIV-specific CD8 T cells, suggesting that these cells have an active antiviral effect^{36,221}; animal model data support this conclusion.^{194,356} When CD8 T cells are removed by administration of a CD8-specific monoclonal antibody in animals with chronic SIV infection, viral load dramatically increases, and subsequently declines again coincident with the reemergence of these cells. If CD8 T cells are depleted before acute infection in this model then viral load remains at the initially high levels.³⁵⁶ Therefore, it is clear that these cells play an ongoing role in viral containment. Because the latent viral reservoir remains invisible to these responses, CD8 T cells are unable to eradicate HIV.

The breadth and magnitude of CD8 T-cell responses can vary widely among infected persons, as measured by the ability of these cells to secrete IFN- γ following recognition of their cognate epitope. Despite animal model data showing the clear role of these cells in immune containment, other studies have failed to provide strong and consistent evidence that these responses are associated with suppression of the plasma viral load in humans. Responses have been observed to all nine HIV viral proteins and, in most persons, an average of more than a dozen viral peptides are simultaneously targeted.^{4,25} The total percent of CD8 T cells directed against HIV in the chronic phase of infection can be 25% or higher, and yet, the magnitude of these responses does not correlate with control of viremia.²⁵ One relatively consistent finding is that targeting of HIV-1 Gag over other viral proteins is associated with a lower viral load.^{326,435} Although initial animal studies suggested that targeting of proteins expressed early in the viral life cycle (e.g., Nef) might be advantageous, this finding has not been consistently borne out in larger studies in humans, although it is clear that Nef is one of the most common viral antigens targeted by the CD8 T-cell response during acute HIV infection.^{117,146} Data also indicate

that the HLA B alleles, as opposed to the A and C alleles, play the dominant role in modulating viral load,²¹³ again suggesting a key role for CD8 T cells in immune containment, but debate continues whether this is cause or effect.

Whereas these data clearly indicate that CTLs are involved in viral control, it is often difficult to determine their exact contribution in human studies. One reason for this difficulty is that both the virus and the CTL response are constantly adapting to each other over the course of the infection. Although each person has up to six different class I alleles to present viral peptides at the cell surface, only a subset of these are used in acute infection.⁶ That initial immune response is therefore narrowly directed to only a few epitopes, most of which rapidly escape, and other epitopes become targeted as the response broadens over time well after viral set point is reached.⁹ In addition, it is clear that not all CD8 T cells are the same, and based upon their different phenotypes and functions, they may have profoundly different antiviral effects.^{121,241}

Virus-Specific CD4 T Cells

The optimal production of antibodies and the function of CD8 T cells depends on the presence of virus-specific CD4 T cells.⁹² The magnitude of these responses, as measured by IFN- γ production, is consistently much lower than the CD8 T-cell responses, and a small number of peptides are recognized by most individuals.^{25,326} In contrast to the wide spectrum of responses mediated by CD8 T cells, the adaptive CD4 T-cell response is primarily directed against the Gag protein, for reasons that are unclear. In the early stage of acute infection, a robust induction of HIV-specific CD4 T cells occurs, and these cells clearly provide help to CD8 T cells, as evidenced by the ability of CD8 T cells in acute infection to proliferate *in vitro* in response to cognate epitope recognition.²³⁶ The ability of CD4 and CD8 T cells to proliferate *in vitro* is lost over the first few months of untreated infection, but the acquired defect in CD8 T-cell proliferation can be restored *in vitro* by the addition of CD4 T cells obtained at the time of acute infection or by IL-2.^{185,236} Although HIV-specific CD4 T-cell function has been augmented through therapeutic interventions (vaccination, treatment interruptions, and IL-2 therapy), none of these approaches has led to improved virologic or clinical outcomes.^{3,185,207,340,344,346}

CD4 T cells can be classified based on their major functions into multiple lineages, including T helper 1, T helper 2, T helper 17, follicular T helper, and T regulatory. Most HIV-specific CD4 T cells fall within the T helper 1 category based on their secretion of IFN- γ , but their overall function appears to be impaired.^{161,185} The fact that HIV preferentially infects and depletes HIV-specific CD4 T cells may partially explain the low frequency of HIV-specific CD4 T cells and their inability to adequately coordinate humoral and CD8 T-cell responses to HIV.¹⁰² In addition, the phenotype and function of opportunistic pathogen-specific CD4 T cells may affect their susceptibility to infection and depletion by HIV, thereby explaining some of the variation in onset of different opportunistic infections.^{52,139} Specifically, CD4 T cells that express β chemokines (which block HIV entry by binding to CCR5) are more resistant to HIV infection and depletion than those that do not.^{52,139}

Host Genetics and Viral Control

One of the strongest predictors of disease progression is the HLA type of the host. The HLA class I alleles B*27 and B*57 are associated with low viral load and prolonged asymptomatic

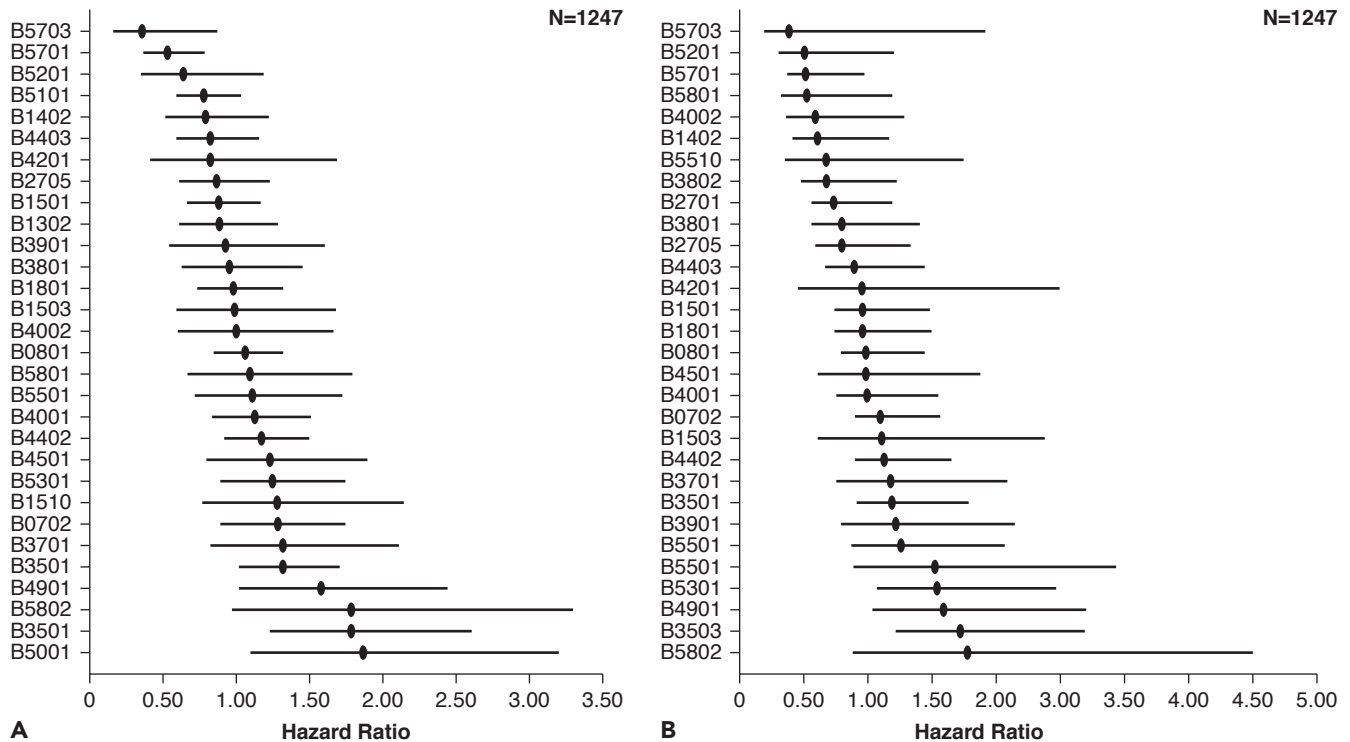

FIGURE 50.4. Relative hazard of disease progression by human leukocyte antigen (HLA) class I type. A: Relative hazard of progression to a CD4 count of less than 200/mm³. **B:** Relative hazard of progression to acquired immunodeficiency disease syndrome (AIDS) by the 1987 AIDS defining criteria.

infection,²⁰¹ although additional alleles have also been shown to affect viral load (Fig. 50.4). Other HLA alleles have been associated with more rapid disease progression, in particular a subtype of the HLA B35 allele referred to as *HLA B35 px*.¹³³ It is now clear that the HLA B alleles are dominant in terms of having an impact on viral load.²¹³ On a population level, clear evidence indicates viral imprinting by host CD8 T-cell responses: Persons with certain HLA alleles have a significantly increased prevalence of certain viral polymorphisms that appear to be driven by immune escape.²⁰⁸ Animal studies have shown clearly that the major histocompatibility complex (MHC) type can influence both disease progression and the relative contribution of cellular and humoral immune responses to viral control.²⁵¹ Immunization of humans with candidate HIV vaccines has also shown HLA-related differences in immunogenicity.²⁰² Remaining to be identified are the precise mechanisms whereby these alleles mediate a protective or detrimental effect, or enhance immunogenicity of candidate vaccines, or whether this represents a linkage to some other genetic factor that modulates outcome. In addition to HLA alleles, other genetic factors may also have an impact on disease progression, and are discussed below.

Reasons for Immune Failure

Functional Defects

Why is it that the immune system is unable to contain HIV replication, despite detection of huge numbers of HIV-specific immune cells? An increasing amount of evidence suggests that the problem is not in the number of antiviral cells but in their function, and that most HIV-specific CD8 T cells

have some degree of functional impairment. The list of these potential defects is long, and includes lack of ability to express multiple cytokines simultaneously, to kill infected target cells, or at least to inhibit HIV replication, proliferate, and fully mature.^{26,91,170,171,272} Which of these aspects of the CD8 T-cell response in chronic HIV infection is a cause as opposed to an effect of ongoing viral replication is often unclear. What is clear, however, is that chronic antigenic stimulation by persistent viruses can lead to exhaustion of CD8 T cells by preventing them from completing the normal progression to renewable memory cells.^{416,417} In addition, studies in a murine model of chronic viral infection with many similarities to HIV infection in humans suggest that the expression, on CD8 T cells, of molecules associated with T-cell regulation (i.e., programmed death 1 [PD-1], 2B4, CD160, lymphocyte activation gene 3 [LAG-3]) may be affected by the persistent antigenic stimulation of chronic viremia, rendering those CD8 T cells ineffective in clearing virus.^{21,28} Studies of HIV-specific T cells have generally confirmed the presence of aberrant expression of co-regulatory molecules that can adversely affect HIV-specific CD8 T-cell function and longevity.^{90,307,396,429} Co-regulatory molecule expression can also be aberrant on CD4 T cells, thereby imparting indirect effects on the CD8 T-cell response.²⁰⁶

Immune Escape

The role of CD8 T cells as an antiviral mechanism is clearly implied by studies showing viral mutations arising within targeted CD8 T-cell epitopes. Studies clearly demonstrate substantial immune selection pressure as evidenced by frequent

FIGURE 50.5. Changes in plasma human immunodeficiency virus type 1 (HIV-1) RNA level, CD4⁺ cell count, HIV-1-specific antibody titers, and HIV-1-specific cellular immune responses over the course of HIV-1 infection.

polymorphisms linked to specific HLA alleles²⁰⁸ and the accumulation of HLA-associated changes during acute HIV infection. Of note, the effectiveness of CD8 T-cell responses has been linked to the fitness cost associated with viral escape, adding further evidence in support of the fact that HIV-specific CD8 T cells, although functionally impaired, still exert significant antiviral pressure on HIV, even late into infection.⁷⁹

CLINICAL FEATURES

Advancing immunodeficiency caused by the progressive loss of CD4⁺ T lymphocytes underlies the cardinal clinical manifestations of HIV-1 infection. The myriad opportunistic infections and malignancies characteristic of AIDS are a consequence of the resulting profound defect in cellular immunity. In addition,

a number of clinical syndromes are attributable directly to infection of specific organs by HIV-1. The course of HIV-1 disease can be divided into three stages: primary (or acute) infection, chronic (asymptomatic) infection, and advanced disease (AIDS) (Fig. 50.5). The duration of each stage is highly variable and can be altered by antiretroviral therapy. Several systems for classifying the different stages of HIV-1 disease have been developed, the most widely used of which include those developed by the CDC (Table 50.2) and the World Health Organization (WHO).^{56,426} Although these classification systems are valuable epidemiologic tools, their role in the assessment and clinical management of individual patients has been more limited.

Primary Infection

Acquisition of HIV-1 infection is accompanied by relatively nonspecific symptoms of an acute viral illness in approximately

TABLE 50.2 CDC Classification System for HIV Infection

CD4 cell categories	Clinical categories		
	A Asymptomatic, lymphadenopathy, or acute infection	B Symptomatic, ^a not category A or C	C Clinical AIDS ^b
>500/mm ³ (>29%)	A1	B1	C1
200–499/mm ³ (14–28%)	A2	B2	C2
<200/mm ³ (<14%)	A3	B3	C3

^aExamples of these symptoms include bacillary angiomatosis; thrush; vulvovaginal candidiasis; cervical dysplasia or carcinoma *in situ*; constitutional symptoms such as fever or diarrhea of >1 month duration; oral hairy leukoplakia; multidermatomal or recurrent herpes zoster; immune thrombocytopenic purpura; listeriosis; pelvic inflammatory disease; and peripheral neuropathy.

^bCandidiasis of the esophagus or respiratory tract; invasive cervical cancer; extrapulmonary coccidioidomycosis; cryptosporidiosis; extralymphatic cytomegalovirus infection; herpes simplex with mucocutaneous ulcer >1 month duration, or bronchitis, pneumonitis, or esophagitis; extrapulmonary histoplasmosis; HIV-associated dementia; CNS lymphoma; non-Hodgkin's lymphoma; pulmonary tuberculosis; disseminated *M. tuberculosis*, *M. avium* complex, or *M. kansasii* infection; nocardiosis; *Pneumocystis jirovecii* pneumonia; recurrent bacterial pneumonia; progressive multifocal leukoencephalopathy; recurrent *Salmonella* septicemia; extraintestinal strongyloidiasis; toxoplasmosis.

Adapted from the Centers for Disease Control and Prevention. 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR Morbid Mortal Wkly Rep* 1992;41 (RR-17):1–19.

50% to 70% of infected individuals.¹⁹⁸ Symptoms, which usually begin 2 weeks after exposure, frequently include fever, pharyngitis, headache, arthralgias, myalgias, malaise, and weight loss.^{85,167} A nonpruritic, maculopapular rash on the face and trunk occurs in up to 70% of cases.³⁹⁵ In addition, generalized lymphadenopathy is a frequent finding. Mucocutaneous ulceration and weight loss help distinguish primary HIV-1 infection from other viral syndromes.^{125,167} Aseptic meningoencephalitis is the most common neurologic manifestation of primary HIV-1 infection.³⁹⁵ Symptoms of primary infection resolve within 3 to 4 weeks in most patients. Persistence of symptoms beyond 8 to 12 weeks, along with a severely depressed CD4+ T-lymphocyte count and high plasma HIV-1 RNA levels may predict more rapid progression of disease.

Laboratory characteristics of primary HIV-1 infection include lymphopenia and a decrease in the absolute CD4+ T-lymphocyte count, usually accompanied by an increase in circulating activated CD8+ T cells.⁷⁵ Other hematologic abnormalities are unusual, except for mild thrombocytosis. Modest elevations in serum aspartate transaminase and alkaline phosphate may be present, but clinically significant hepatitis is uncommon.³⁹⁵ Plasma HIV-1 RNA titers generally peak 1 week following the onset of symptoms, averaging 10^6 to 10^7 copies/mL, and decline to steady-state levels (between 10^3 and 10^5 copies/mL) by 2 months after infection.^{237,246}

Chronic Infection

Following resolution of primary infection and establishment of a virologic *quasi-steady state*,¹⁷⁵ a prolonged period of asymptomatic chronic infection ensues. Although most patients remain asymptomatic during much of this phase, ongoing viral replication and CD4 lymphocyte depletion make the term *clinical latency* inappropriate. The loss of CD4 T cells proceeds at an average rate of 30 to 60 cells/mm³/year, although CD4 cell counts can remain stable for several years before a period of rapid decline.²⁶⁶ A small proportion of patients (<1%) experience progression to AIDS within 1 to 2 years.^{280,310} Rapid progression may be associated with transmission of syncytium-inducing (SI) variants of HIV-1 (i.e., viruses that use the CXCR4 coreceptor, also known as *X4 viruses*).^{64,224,287}

Fatigue and lymphadenopathy are noted by many patients during this otherwise asymptomatic phase of HIV-1 infection. Minor clinical events, such as oral hairy leukoplakia (caused by Epstein-Barr virus infection of oral epithelial cells), oral and vaginal candidiasis, herpes zoster, and a variety of other dermatologic conditions may be early signs of clinical progression. With advancing disease, night sweats and weight loss become more common.

A variety of systemic manifestations of HIV-1 infection involving nearly every organ system can occur during the chronic phase of disease. Remission in response to antiretroviral therapy suggests a direct role for HIV-1 in the pathogenesis of these disorders. Dermatologic conditions are particularly common among HIV-1-infected individuals, including seborrheic dermatitis, papular pruritic eruption, and eosinophilic folliculitis.⁷⁶ Neurologic manifestations include disorders of both the central nervous system (CNS) and peripheral nervous system, in addition to opportunistic infections and malignancies of the CNS. AIDS dementia complex and distal symmetric polyneuropathy, which occur in up to 27% and 35% of patients, respectively, are among the most frequently encountered HIV-related

neurologic complications.^{373,377} Wasting associated with HIV infection remains highly prevalent in resource-limited settings and is an independent predictor of mortality.²⁵⁰ Anorexia, malabsorption, and inappropriate nutrient utilization all contribute to the loss of lean body mass in patients with AIDS.^{154,220}

Other organ system-specific complications of HIV infection include nonspecific interstitial pneumonitis and lymphocytic interstitial pneumonitis, disorders of the gastrointestinal tract, endocrine dysfunction, anemia and neutropenia, immune-mediated thrombocytopenia, and a variety of rheumatologic syndromes. In addition, HIV-associated nephropathy leading to renal insufficiency is particularly common among African Americans and injection drug users.^{390,422}

Advanced Disease

Opportunistic infections and malignancies are rare in HIV-infected persons with CD4 counts above 500 cells/mm³, but increase as the CD4 count declines below this benchmark. Oral candidiasis, pneumococcal infections, tuberculosis, and reactivation of herpes simplex and varicella zoster viruses become more common. The risk of life-threatening complications, including *Pneumocystis jirovecii* (formerly, *P. carinii*) pneumonia, candida esophagitis, disseminated histoplasmosis and other systemic fungal infections, toxoplasma encephalitis, and cryptococcal meningitis increases substantially once the CD4 lymphocyte count drops below 200 cells/mm³.²⁵⁸ Opportunistic infections, such as disseminated *Mycobacterium avium* complex infection; reactivation of cytomegalovirus (CMV) infection, cryptosporidiosis, and microsporidiosis; and progressive multifocal leukoencephalopathy caused by JC virus reactivation, are all indicative of a profound defect in cellular immunity and usually occur at CD4 counts below 50 cells/mm³. Malignancies associated with AIDS generally are related to underlying viral infection, including Kaposi sarcoma (KS) caused by infection with human herpes virus 8; lymphomas associated with Epstein-Barr virus infection; and cervical and anal carcinoma associated with human papilloma virus infection. Although potent antiretroviral therapy has clearly reduced the risk of KS and non-Hodgkin lymphoma, the effect on Hodgkin lymphoma is less clear.^{32,33,370} Whereas the incidence of lung cancer is also increased in persons with HIV infection, age-adjusted rates of other malignancies (e.g., breast and prostate cancer) are comparable to those found in the general population.^{152,369}

Non-AIDS Complications of HIV Infection

A growing number of end-organ complications not traditionally considered “AIDS-defining” events have been recognized to occur more frequently in HIV-1–infected patients.^{253,286} These include an increased risk of cardiovascular disease, non-AIDS defining malignancies, HIV-associated neurologic dysfunction (HAND), and HIV-associated nephropathy (HIVAN), and may also include loss of bone mineral density (BMD) and other changes typically associated with increasing age, suggesting that HIV-1 infection may accelerate the aging process more generally.

With respect to cardiovascular risk, a number of studies suggest increased risk of myocardial infarction in HIV-1–infected patients as compared to control populations matched for traditional cardiovascular risk factors such as age, family history, hyperlipidemia, hypertension, diabetes, and smoking.^{177,286,398} More striking is the finding that interrupting antiretroviral

therapy significantly increases the risk of cardiovascular events, independent of CD4 cell count.^{106,313} This increased risk was correlated with an increase in plasma levels of inflammatory markers such as IL-6 and high-specificity C-reactive protein (hsCRP).^{223,347} In addition, a number of studies have shown adverse changes in surrogate markers associated with cardiovascular risk such as flow-mediated vasodilatation, carotid intima-media thickness, and coronary artery calcification in patients with HIV-1 infection.^{82,153} The extent to which these changes can be prevented or reversed by antiretroviral therapy is an active area of current research.

Patients with HIV-1 infection also show lower BMD and an increased risk of fractures compared to age-matched, uninfected controls.³⁹⁷ The causes of HIV-associated loss of BMD are poorly understood and most likely are multifactorial, including increased immune activation and inflammation, renal tubular dysfunction, low vitamin D levels, and other endocrine abnormalities.¹⁰ Whether vitamin D levels should be monitored in all HIV-infected patients, and at what level to offer supplementation, remains an area of controversy.

Determinants of Disease Progression

Numerous viral and host factors contribute to determining the rate of HIV disease progression. The plasma HIV-1 RNA level, or viral load, reflects the rate of virus replication and is a powerful independent prognostic factor for the risk of disease progression.^{267,304} Data from the MACS show that in the absence of antiretroviral therapy individuals with plasma HIV-1, RNA levels greater than 100,000 copies/mL 6 months after seroconversion are 10 times more likely to progress to AIDS within 5 years than are those with lower steady-state levels of viremia.²⁶⁵ Similarly, for patients with established HIV-1 infection, a steady-state viral load of more than 30,000 copies/mL is associated with a more than fivefold greater risk of disease progression within 3 years as compared with patients with viral loads of 3,000 to 10,000 copies/mL.²⁶⁶

According to a Poisson regression model based on data from the Concerted Action on Seroconversion to AIDS and Death in Europe (CASCADE) collaboration of 22 cohorts from Europe, Canada, and Australia, in the absence of combination antiretroviral therapy the 6-month risk of AIDS for a 25-year old patient with a CD4 cell count of 350/mm³ ranges from 0.6% at a viral load of 3,000 copies/mL to 2.5% at a viral load of 300,000 copies/mL.³¹¹ At a CD4 count of 100 cells/mm³, the AIDS risk at the same viral loads increases to 3.7% and 14.5%, respectively. The risk of disease progression has been reduced substantially since the introduction of potent combination antiretroviral therapy.¹⁰⁵ Progression to AIDS among persons infected with HIV-2 proceeds at a significantly slower rate as compared with infection with HIV-1.^{188,260} Epidemiologic and cohort studies show that HIV-2 infection generally results in lower steady-state levels of viremia (10³ copies/mL) and a more gradual decline in CD4 cell counts.^{15,24,188}

Age at the time of infection is an independent risk factor for disease progression, with older persons being at significantly greater risk, perhaps as a consequence of diminished thymic reserve.^{89,309} The role of gender in determining disease progression is less clear. Most studies show that HIV-1-infected men and women progress to AIDS at similar rates.^{134,273} Early in the course of infection, however, women tend to have significantly lower plasma HIV-1 RNA levels men.^{11,12,111} This difference dis-

appears as disease progresses. Because overall progression rates are comparable between the sexes, these observations imply that compared with men, women experience HIV-1 disease progression at lower viral loads. Whether to initiate antiretroviral therapy at lower levels of viremia in infected women than in men remains controversial (see below).

Although virus replication, and consequently viral load, is the engine that drives progression to AIDS, the CD4 cell count is the most useful marker for predicting the immediate risk of developing particular opportunistic infections.¹⁰⁵ Moreover, differences in viral load explain only a small fraction of the variability in rates of CD4 cell decline in patients not receiving antiretroviral therapy,³⁴³ suggesting that other factors such as immune activation triggered by translocation of microbial products across a damaged intestinal mucosa drive CD4 cell loss in HIV infection (see Pathogenesis). Indeed, the proportion of activated CD8+ T cells, measured as the percentage of cells expressing CD38, predicts the risk of disease progression independently of viral load and CD4 count.^{31,142,143,240} Levels of IL-6 and hsCRP are elevated in patients with HIV infection and independently predict the development of opportunistic diseases.³⁴²

The role of chemokine receptor tropism in determining the rate of disease progression remains unresolved. The prevalence of X4 variants increases with decreasing CD4 cell count, and several studies show a significantly increased risk of disease progression among patients with X4 (SI) virus.^{45,217,278,362} Macaques infected with a simian-HIV (SHIV) (SIV/HIV chimera) that expresses an X4 HIV-1 envelope show rapid depletion of CD4 cells, suggesting a causal role of X4 viruses in rapid disease progression.^{178,288} X4 variants, however, emerge in only half of patients who progress to AIDS.^{38,336} The long interval between infection and emergence of X4 viruses in most patients argues for strong selection against X4 viruses early in the course of HIV disease. Therefore, the possibility that emergence of X4 variants is a consequence, rather than a cause, of advancing immunodeficiency remains a plausible alternative explanation for the apparent association of X4 virus with disease progression. The development of chemokine receptor antagonists as a novel class of antiretroviral agents may provide new tools to address this important pathogenesis question.

The risk of disease progression is moderated also by a variety of host genetic factors. Among the most important are polymorphisms in the genes encoding the chemokine co-receptors and their ligands, and in the HLA genes. HIV-1 uses one of two chemokine receptors as co-receptors for virus entry into CD4 cells: CCR5 or CXCR4.^{97,103,113} Approximately 10% of Caucasians carry a defective allele that has a 32-base pair (bp) deletion in the CCR5 gene (*CCR5Δ32*); 1% are homozygous for this deletion and resist infection by R5 viruses.^{239,352} Infected individuals who are heterozygous for the *CCR5Δ32* allele have a slower rate of disease progression than do those who are homozygous for the wild-type allele.⁹⁴ This effect is limited to patients with R5 strains of HIV-1, presumably because syncytium-inducing viruses use the CXCR4 receptor.^{40,270} A mutation in the CCR2 gene, *CCR2-64I*, likewise reduces the rate of disease progression,^{219,376} possibly by delaying emergence of X4 virus.⁴⁰³ By contrast, mutations in the promoter region of CCR5 (*CCR5 P1*) are associated with accelerated disease progression.²⁵⁶ Other analyses have failed, however, to show a significant effect of CCR5 and CCR2 genotype after

controlling for CD4 cell count, plasma HIV-1 RNA level, and viral tropism.^{141,184}

Copy number of the gene encoding the natural ligand for CCR5 (CCL3L1, previously known as MIP-1 α) also influences the rate of disease progression. Higher *CCL3L1* copy number is associated with a lower risk of progression, which is most pronounced in patients with polymorphisms that reduce the level of functional CCR5 on the cell surface.¹⁴⁵ Variable effects on progression have been noted for the *SDF1-3'A* polymorphism, which affects the untranslated region of the mRNA encoding stromal-derived factor (SDF-1, also known as CXCL12), the natural ligand of CXCR4.^{86,145,421}

Several studies have related host HLA haplotype to the rate of HIV disease progression. For example, presence of the HLA-B27 and B57 alleles is associated with slow progression.^{8,112,305} Conversely, patients carrying class I alleles B*35 or Cw*04 progress to AIDS significantly more rapidly than do those lacking these alleles.^{51,133} Maximal heterozygosity at HLA class I loci A, B, and C is associated with delayed onset of AIDS.²⁰¹ Given that HLA antigen class I molecules play an essential role in antigen presentation to CD8+ CTL, these findings provide strong, albeit indirect, evidence for the importance of CTL in moderating the rate of HIV disease progression.

Variation in the killer immunoglobulin-like receptor (KIR) genes also affects the course of disease. These receptors are found on NK cells and regulate NK activity by recognition of certain HLA class I molecules on the surface of target cells.⁴⁰⁴ The effect of KIR alleles appears to be related to the presence or absence of specific HLA-B or HLA-C alleles.¹³⁷ For example, when present together with the HLA-B Bw4-80Ile allele, the activating KIR allele *KIR3DS1* is associated with delayed disease progression.²⁵⁷ By contrast, in the absence of HLA-B Bw4-80Ile, the presence of *KIR3DS1* is associated with more rapid disease progression. Similarly, presence of the inhibitory KIR allele *KIR3DL1* together with HLA-B*57S is highly protective against disease progression.²⁴⁴ The *KIR2DS2* allele appears to be associated with more rapid CD4 decline over time, but has no effect on viral load, whereas HLA-B*5701 and B*2705 alleles are associated with significantly lower levels of viremia.¹³⁶

Co-infecting viral pathogens have varied effects on the rate of disease progression. Patients with CMV viremia were twice as likely to experience disease progression and four times more likely to die.³⁷⁹ Asymptomatic CMV replication may also contribute to ongoing immune activation.¹⁸¹ Although the course of both hepatitis B (HBV) and hepatitis C virus (HCV) infection is worse in patients with HIV-1 infection, the effect of hepatitis co-infection on AIDS progression is less clear, with some studies suggesting accelerated progression of HIV-1 infection among co-infected patients and other studies showing no effect.^{61,350,389,392}; overall, the evidence suggests no significant effect of either HBV or HCV coinfection on the course HIV-1 infection.³⁴¹ By contrast, coinfection with the nonpathogenic GB virus C appears to have a protective effect against AIDS progression, but the mechanism of this protection is obscure.^{290,394,420}

DIAGNOSIS

The occurrence of opportunistic infections such as *P. jirovecii* pneumonia, candida esophagitis, cryptococcal meningitis, toxoplasmosis, or chronic ulcerative herpes simplex in the

absence of a known cause of immunodeficiency should raise the possibility of HIV-1 infection. Recurrent or disseminated varicella zoster infection, pneumococcal infection in a young adult, oral or recurrent vulvovaginal candidiasis, disseminated papillomavirus infection, persistent fever, night sweats, lymphadenopathy, weight loss, and chronic diarrhea all may be evidence of infection with HIV-1. A diagnosis of HIV-1 infection also should be considered in patients with unexplained lymphopenia, anemia, or neutropenia, and in cases of idiopathic thrombocytopenia.

The differential diagnosis of acute HIV-1 infection is broad, and includes other viral syndromes, such as acute Epstein-Barr virus, CMV, adenovirus, influenza, and enterovirus infection that can be associated with fever, myalgias, rash, lymphadenopathy, pharyngitis, aseptic meningitis, or lymphopenia. Acute Lyme disease, secondary syphilis, rickettsial infection, anaplasmosis, and babesiosis all have features in common with primary HIV-1 infection, but are readily excluded by appropriate laboratory tests.

Laboratory Diagnosis

The laboratory diagnosis of HIV infection usually is made by detection of HIV-1 or HIV-2 antibodies by enzyme-linked immunosorbent assay (ELISA), chemiluminescence, or rapid antibody test. The mean time to seroconversion during acute HIV infection is 25 days.⁴⁸ Antibodies to HIV become detectable within 6 to 12 weeks of infection in most infected individuals, and in virtually all patients within 6 months.^{126,176} The time to serologic detection of HIV after initial infection can be reduced by 7 days through the use of “4th generation” diagnostic tests, which combine detection of HIV antibodies and core (p24) antigen.^{108,298} In addition to the standard HIV ELISA, rapid diagnostic tests have been developed.^{166,291,374} The simplicity and wide range of operating temperature for certain of these assays make them particularly well-suited for use in point-of-care testing (e.g., a hospital emergency department or physician office) and in resource-limited settings,^{203,402} but specificity of these rapid tests may be lower than expected when applied to populations with a low prevalence of HIV infection.⁴⁰⁷

Sera that test positive are tested again to verify the initial result; repeatedly reactive sera are then tested by a confirmatory assay, usually a western blot, to ensure that reactive antibodies are directed against HIV antigens. Antibodies against the Gag proteins (p17, p24, p55) appear earliest in the course of HIV-1 infection,³²⁸ but decrease in titer with progression of HIV-1 disease, whereas antibodies to envelope (gp160 or gp120/gp41) usually persist even in advanced stages of HIV-1 disease. The sensitivity of commercial HIV-1 ELISA kits using serum from individuals with documented HIV-1 infection ranges from 98.1% to 100%,³³⁰ whereas specificity in populations with a low prevalence of HIV-1 infection ranges from 99.6% to 100.0%.^{186,293} Combined use of the HIV-1 ELISA and western blot results in a specificity approaching 100%. In settings where HIV prevalence exceeds 5%, confirmation of an initial rapid HIV antibody test by a second test that uses different antigens can serve to make a diagnosis of HIV infection.⁵⁷

The sensitivity of HIV-1 ELISA for detection of HIV-2 ranges from 50% to 93%.^{18,98} The combination HIV-1–HIV-2 antigen sandwich ELISA used by blood banks to screen simultaneously for HIV-1 and HIV-2 antibodies has a sensitivity

of 99.7% for detection of HIV-1 and 99.5% for detection of HIV-2.¹⁸

The diagnosis of primary HIV-1 infection before seroconversion depends on detection of HIV-1 capsid (p24) antigen or HIV-1 RNA in plasma. The sensitivity and specificity of the p24 antigen assay for diagnosis of acute HIV-1 infection range from 79% to 89% and 99% to 100%, respectively.^{85,167} Quantitative HIV-1 RNA assays are highly sensitive (100%), but because of occasional false-positive findings, tests have a specificity of only 95% to 97%.^{85,167} Plasma HIV-1 RNA levels generally exceed 10,000 copies/mL during acute infection, and most false-positive findings generally have values below 3,000 copies/mL.¹⁶⁷ Therefore, diagnostic accuracy of quantitative plasma HIV-1 RNA assays for diagnosing primary HIV-1 infection can be improved if only values that exceed 5,000 copies/mL are considered true positives.¹⁶⁷ Qualitative plasma HIV-1 RNA tests may prove useful in this setting, but have not been extensively evaluated for this purpose.³³¹

Serologic testing of infants born of mothers infected with HIV-1 is complicated by the presence of maternal anti-HIV antibodies that decay over 12 to 15 months. Persistence of antibody beyond 15 months of age is evidence of HIV-1 infection in the infant.⁵⁴ Two negative antibody tests obtained at least 1 month apart in infants older than 6 months of age effectively exclude HIV-1 infection. Earlier diagnosis depends on detection of HIV-1 RNA in plasma or HIV-1 proviral DNA in peripheral blood mononuclear cells. A DNA polymerase chain reaction (PCR) test is positive in approximately 40% of infected children by age 48 hours, and in 93% of infected children by age 14 days.¹⁰⁴ A qualitative HIV-1 RNA test based on

transcription-mediated amplification showed 100% sensitivity and greater than 99% specificity as compared to DNA PCR for infant diagnosis of HIV-1 infection using whole blood or dried blood spots, respectively.³⁸⁶

TREATMENT

The advent of potent combination antiretroviral therapy has had a profound influence on the course of HIV-1 infection in the developed world, where AIDS-related mortality has decreased by more than 80% since the introduction of combination therapy in the mid-1990s.^{105,179,295,323,358} (Fig. 50.6). Premature mortality among HIV-infected persons in the developed world now shows a dichotomous pattern: AIDS-related causes continue to account for deaths among those not receiving antiretroviral therapy, whereas liver-related deaths, including mortality from hepatitis C virus coinfection, account for the preponderance of premature deaths among those receiving adequate antiretroviral therapy.^{34,80,231,350} Thirty antiretroviral drugs and drug combinations in six different classes are approved for the treatment of HIV-1 infection (Table 50.3), with more in clinical development. The experience with antiretroviral therapy serves as a model for the feasibility of treating chronic viral infections, and establishes important paradigms that are being applied to the treatment of other chronic infections such as HBV and HCV.

Targets for Antiretroviral Drugs

The replication cycle of HIV-1 involves multiple steps, many of which have been successfully exploited as targets

FIGURE 50.6. Estimated number of acquired immunodeficiency disease syndrome (AIDS) diagnoses and deaths and estimated number of persons living with AIDS diagnosis and living with diagnosed or undiagnosed human immunodeficiency virus (HIV) infection among persons aged 13 years or older in the United States, 1981–2008. (Centers for Disease Control and Prevention. HIV surveillance—United States. 1981–2008. *MMWR Morbid Mortal Wkly Rep* 2011;60:689–693.)

TABLE 50.3 Generic Names and Common Abbreviations for FDA-Approved Antiretrovirals (2011)

Nucleoside reverse transcriptase inhibitors (NRTIs)		Protease inhibitors (PIs)	
Abacavir	ABC	Amprenavir ^a	APV
Emtricitabine	FTC	fos-Amprenavir	fAPV
Didanosine	ddI	Atazanavir	ATV
Lamivudine	3TC	Darunavir	DRV
Stavudine	d4T	Indinavir	IDV
Zalcitabine	ddC ^a	Lopinavir ^b	LPV
Zidovudine	ZDV	Nelfinavir	NFV
		Saquinavir	SQV
		Ritonavir ^c	RTV
		Tipranavir	TPV
Nucleotide RT inhibitor (NtRTI)		Fusion inhibitor	
Tenofovir	TDF	Enfuvirtide	ENF
Nonnucleoside RT inhibitors (NNRTIs)			
Delavirdine ^d	DLV		
Efavirenz	EFV		
Etravirine	ETV		
Nevirapine	NVP		
Rilpivirine	RPV		
Integrase strand transfer inhibitor (INSTI)		CCR5 antagonist	
Raltegravir	RAL	Maraviroc	MVC

^aWithdrawn from market by manufacturer.^bAvailable only as co-formulation with ritonavir.^cUsed principally for pharmacologic enhancement of other antiretroviral agents.^dNot recommended and rarely used.

for antiretroviral drug development (Fig. 50.7). The first step in the virus life cycle is virus entry, a multistep process that involves attachment, co-receptor binding, and fusion of the cell and virus membranes. Although earlier attempts at preventing virus attachment by soluble CD4 proved unsuccessful,^{84,359,400} small molecule inhibitors that block the gp120-CD4 interaction show some promise.¹⁶⁰ Potent inhibition of HIV-1 replication has been demonstrated in randomized clinical trials by maraviroc, a small-molecule chemokine receptor antagonist that prevents binding of gp120 to CCR5.^{74,155} Similarly, a humanized monoclonal antibody (ibalizumab) that binds to domain 2 of the extracellular portion of CD4 and acts as a postattachment inhibitor of virus entry has shown potent anti-HIV-1 activity in clinical trials.^{187,225} The efficacy of the fusion inhibitor enfuvirtide (T-20), a synthetic 36-amino acid oligopeptide, was demonstrated in a series of randomized clinical trials.²²⁶ This drug blocks virus fusion by preventing the formation of a six-helix bundle by two heptad repeats (HR-1 and HR-2) in the trimeric gp41 ectodomain.^{418,419}

Inhibition of reverse transcriptase (RT) by substrate analogs (nucleoside and nucleotide RT inhibitors [NRTIs]) and by noncompetitive inhibitors (non-nucleoside RT inhibitors

[NNRTIs]) constitutes the mainstay of most antiretroviral regimens. Because the NRTIs lack a 3'-OH group, once incorporated into the growing complementary DNA (cDNA) strand, they act as chain terminators, bringing reverse transcription to a halt.³⁰⁰ Another feature of the NRTIs is their need for phosphorylation by intracellular nucleoside and nucleotide kinases to generate the active deoxynucleotide triphosphate (dNTP) forms of these drugs. Activity of these kinases can differ between cell types (lymphocyte versus monocyte or macrophage) and their activation state, accounting for variations in drug activity.¹³² Moreover, NRTIs that rely on the same phosphorylation pathway can exhibit antagonism when used in combination, as in the case of zidovudine and stavudine, which both depend on thymidine kinase for their initial phosphorylation.^{163,269,405} The NRTIs have formed the backbone of antiretroviral therapy since the introduction of zidovudine in 1987.

The NNRTIs are a chemically diverse class of drugs that occupy a potential drug-binding pocket in RT distinct from the dNTP binding site. Binding induces conformational changes that essentially inactivate RT¹⁰⁹; in this respect, the NNRTIs can be considered allosteric inhibitors of RT function.³⁸⁰ Currently approved NNRTIs generally are inactive against HIV-2, which lacks tyrosine residues at positions 181 and 188 that are essential for drug binding.³³² Drugs in this class play a central role as preferred agents for first-line regimens and for prevention of mother-to-child transmission.

Inhibition of HIV-1 protease prevents processing of the Gag and Gag-Pol polyprotein precursors into their mature constituents, which comprise the structural proteins of the virus core particle (capsid, matrix, and nucleoprotein) as well as the three virally encoded enzymes (protease, reverse transcriptase, and integrase) required for virus replication. In contrast to inhibitors of virus entry and RT, protease inhibitors do not prevent uninfected cells from becoming infected by HIV-1, but result in the release of noninfectious virions.^{119,196,301} Most protease inhibitors are peptidic or peptidomimetic compounds designed as analogs of the cleavage sites found within the Gag and Gag-Pol precursor proteins. Because of their relatively poor oral bioavailability, most protease inhibitors are coadministered with a low dose of ritonavir, an HIV-1 protease inhibitor that inhibits the 3A4 isozyme of cytochrome P450 (CYP 3A4)²¹⁰; CYP 3A4 is responsible for metabolism of most of these drugs. Protease inhibitors have proved to be highly effective in the treatment of HIV-1 infection as components of initial and subsequent treatment regimens.

Following reverse transcription, the resulting linear double-stranded DNA (dsDNA) molecule must be integrated into the host chromosome. The process of integration, which is catalyzed by the virally encoded integrase, is a multistep process that involves formation of a preintegration complex, nuclear importation, endonucleolytic processing of the 3' ends of the DNA molecule, and a strand-transfer reaction that results in covalent attachment of the viral and cellular DNA (see Chapter 49). The development of appropriate high-throughput screening assays allowed identification of specific inhibitors of the strand-transfer reaction.¹⁶⁵ The efficacy of the integrase inhibitor raltegravir has been demonstrated in phase 3 clinical trials in treatment-naïve²³⁰ and treatment-experienced patients,³⁸³ respectively.

Other potential targets for drug development include the viral accessory proteins (Nef, Rev, Tat, Vif, Vpr, and Vpu), as well as cellular proteins necessary for viral replication. A

FIGURE 50.7. Points of attack in the human immunodeficiency virus type 1 (HIV-1) virus lifecycle for antiretroviral drugs.

number of cellular restriction factors that prevent HIV-1 infection have been described, including APOBEC3G and TRIM-5 α . Both factors constitute a part of the innate cellular defense against viral infection. APOBEC3G, a DNA cytosine deaminase, introduces fatal errors into the nascent viral DNA during reverse transcription, rendering the virus not infectious.²⁴⁹ The HIV-1 protein Vif counteracts the effects of APOBEC3G and could serve as a target for antiviral drug development. Likewise, Vpu counteracts the effects of tetherin, which prevents release of virus particles during the budding process, could also be a target for drug development.³⁰⁶ TRIM-5 α is a component of cytoplasmic bodies that mediate species-specific innate cellular resistance to HIV-1 by modulating early events in the virus replication cycle.³⁸⁷ Many HIV-1 variants appear to protect themselves from restriction factors through an association with the host protein cyclophilin A; derivatives of cyclosporin have demonstrated *in vitro* antiretroviral activity.³⁷⁸ Lens epithelium-derived growth factor (LEDGF), a cellular co-factor of HIV-1 integrase, offers another promising target for drug development.⁶² The identification of more than 250 HIV-dependency factors through a large-scale screen with small interfering RNA (siRNA) provides additional therapeutic targets.³⁹

A variety of gene therapy approaches have been proposed to render CD4 cells resistant to HIV-1 infection. These include the use of ribozymes,⁴²⁴ antisense RNA,¹⁸⁰ or siRNA to silence expression of viral or cellular genes.⁴¹⁵ Preliminary human studies of genetically modified cells expressing zinc-finger nucleases

that disrupt expression of host genes essential for virus replication are underway.⁴⁹ Although these approaches have shown promise in the laboratory, they face formidable challenges in demonstrating efficacy in clinical trials.

Principles of Antiretroviral Therapeutics

The demonstration in 1987 that zidovudine increases survival of individuals with advanced HIV-1 disease¹¹⁸ ushered in the era of antiretroviral therapy (ART). Subsequent development of additional NRTIs created possibilities for combination therapy.^{268,360} The NNRTIs had even greater potency as antiretroviral agents, but rapid emergence of resistance initially hindered their development.^{60,87,162} The discovery of protease inhibitors with a higher genetic barrier to resistance provided sufficiently potent regimens that could achieve durable suppression of virus replication.¹⁵⁶ At the same time, viral dynamics studies demonstrated high rates of HIV-1 replication and turnover of the HIV-1 quasi-species and suggested the inevitable emergence of drug resistance when ART does not completely inhibit replication.^{175,304,413} These observations provided the theoretic basis for use of potent drug combinations with the goal of suppressing plasma HIV-1 RNA levels to below the limits of detection of the most sensitive assays available.¹⁶⁴

Acute (Primary) HIV-1 Infection

Theoretic benefits of ART during primary HIV-1 infection include ameliorating the symptoms associated with acute

infection; reducing the steady-state level of viremia; limiting the pool of resting, latently infected CD4 T cells; preserving immune function generally and HIV-1-specific immune responses in particular; and preventing onward transmission by decreasing virus titers in blood and genital secretions. Although a number of studies have shown significant short-term improvement in virologic and immunologic markers in subjects who initiate ART during primary HIV-1 infection, most of these benefits wane once treatment is discontinued. Viral replication resumes promptly on cessation of therapy, even after prolonged periods of suppression, despite augmentation of HIV-1-specific CD4 and CD8 T-cell responses.^{207,254,344,345}

Previous approaches to the treatment of acute HIV-1 infection were based on the hypothesis that a finite course of ART initiated during acute infection or shortly after seroconversion would have virologic and immunologic benefits that persist after treatment interruption.^{168,406} However, given the risks posed by treatment interruption,¹⁰⁶ this approach no longer seems desirable, and once initiated treatment should be continued indefinitely. Moreover, the shift in treatment guidelines toward recommending initiation of ART at earlier stages of disease increasingly blurs the distinction between treatment of acute and chronic HIV infection. Nevertheless, no consensus exists at present regarding treatment of patients with acute HIV-1 infection or those who have seroconverted within the previous 6 months.²⁹⁹

Chronic HIV Infection

The benefits of ART for patients with chronic HIV infection are well established. The availability of potent, once-daily regimens that are generally well tolerated has made durable suppression of HIV-1 replication an achievable goal for most patients who require ART. A large body of data from randomized control trials and longitudinal cohort studies informs treatment guidelines developed by various groups. The general principles are clear: To be effective, treatment must be sufficiently potent to suppress plasma viremia to below the limits of detection of sensitive assays, and must be sufficiently simple and well tolerated that patients will be capable of adhering to the prescribed regimen with a minimum of missed doses. Because current therapy is incapable of eradicating HIV-1 infection, once such therapy is started most patients will require it lifelong.

There is broad consensus that ART should be offered to HIV-infected patients with CD4 counts of less than 350 cells/mm³, and for those with symptomatic HIV infection or AIDS-defining conditions regardless of CD4 cell count.^{67,138,299,393} Randomized clinical trials support the survival benefits of initiating ART at a CD4 count of 350 cells/mm³, as compared to lower CD4 counts.³⁶⁴ Less agreement exists on whether to treat patients with CD4 counts greater than 350 cells/mm³. Guidelines from the U.S. Department of Health and Human Services (DHHS) and the International AIDS Society-USA recommend initiating ART in patients with CD4 counts below 500 cells/mm³, and suggest considering treating all patients from the time of diagnosis.^{299,393} These recommendations are based on the growing appreciation of the variety of HIV-related complications and end-organ diseases that occur as a consequence of the heightened state of immune activation that accompanies uncontrolled HIV-1 replication, and that may occur independent of immunological status. In addition, analysis of data pooled from several North American cohort

studies of HIV-infected patients shows a survival advantage for those who initiated antiretroviral therapy, even at CD4 counts above 500 cells/mm³, as compared to those who deferred therapy to lower CD4 cell counts.²¹⁵ However, another large cohort study found that the survival difference of early versus deferred antiretroviral therapy is attenuated and no longer statistically significant at CD4 cell counts above 350/mm³.³⁸⁵ Guidelines from other groups such as the European AIDS Clinical Society⁶⁷ and the British HIV Association¹³⁸ generally are more conservative and recommend initiating antiretroviral therapy when the CD4 count falls below 350 cells/mm³.

Preferred regimens include the fixed-dose combination of tenofovir, emtricitabine, and efavirenz, or a fixed-dose combination of tenofovir/emtricitabine plus a ritonavir-boosted protease inhibitor (atazanavir or darunavir) (Table 50.4). Randomized trials have shown the efficacy and long-term durability of regimens that include efavirenz or a boosted protease inhibitor.^{157,173,274,292} The combination of tenofovir/emtricitabine plus the integrase inhibitor raltegravir is also considered a preferred regimen, but long-term experience with this regimen is more limited.²³⁰ Because recommendations change as new data become available, readers should consult the *Department of Health and Human Services Guidelines for Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents*, which is updated regularly and may be found at <http://aidsinfo.nih.gov>.

Pharmacologic interactions between different antiretroviral drugs, or between antiretroviral drugs and drugs used to treat common co-infections, significantly complicate the use of ART in many settings. Most troublesome are the interactions of NNRTIs and protease inhibitors (PIs) with the cytochrome P450 (CYP) system. Perhaps the greatest challenge is the difficulty of combining standard antituberculosis regimens with first-line ART because of the profound induction of CYP by rifampin, an essential component of antituberculosis regimens.²³²

Virologic and Immunologic Effects of Antiretroviral Therapy

A brisk decrease in plasma HIV-1 RNA levels should be expected following treatment initiation, with at least a 1-log₁₀ reduction within 14 days. In most patients, plasma HIV-1 RNA should fall to less than 50 copies/mL by week 16 to 24, depending on the starting viral load. Failure to achieve the expected drop in plasma viremia raises concerns regarding the degree of treatment adherence or presence of drug-resistant virus. The initial rapid decay in plasma viremia reflects the half-life of productively infected, activated cells.³⁰⁴ By contrast, the decay in latently infected resting memory (CD45RA⁻RO⁺) CD4 cells is almost imperceptible.¹¹⁵ Replication-competent HIV-1 can be recovered from these latently infected cells by the use of sensitive culture techniques.^{63,116,423} In one study, the half-life of latently infected resting memory CD4 cells was estimated to be as long as 43 months, whereas a second study documented a half-life of only 6 months.^{115,430} Decay rates of these latently infected memory cells were significantly faster in patients with consistent suppression of plasma HIV-1 RNA to less than 50 copies/mL while receiving potent ART as compared with patients who experienced transient episodes of viremia.^{327,430}

The mechanism by which the reservoir of latently infected resting memory cells persists in patients on suppressive ART remains controversial. In some studies, envelope sequences obtained at intervals show signs of evolution, which has been

^aRegimens with optimal and durable efficacy, favorable tolerability and toxicity profile, and ease of use. The preferred regimens for nonpregnant patients are arranged by order of FDA approval of components other than nucleosides, thus, by duration of clinical experience.

^bFTC and 3TC may be used interchangeably in each of the regimens listed in the table.

^cATV/r, DRV/r, LPV/r and FPV/r denote dosing of the indicated protease inhibitor together with pharmacologic enhancement by low-dose ritonavir.

^dRegimens that are effective and tolerable but have potential disadvantages compared with preferred regimens. An alternative regimen may be the preferred regimen for some patients.)

The following combinations in the recommended list above are available as fixed-dose combination formulations: ABC/3TC, EFV/TDF/FTC, LPV/r, TDF/FTC, and ZDV/3TC. Abbreviations of drug names are given in Table 50.3.

Adapted from DHHS Guidelines for the Use of Antiretroviral Agents in HIV-1-Infected Adults and Adolescents (<http://www.aidsinfo.nih.gov/ContentFiles/AdultandAdolescentGL.pdf>).

taken as evidence of replication.⁴³⁰ In other studies, failure of resistance mutations to emerge over time has been taken as evidence against replication in this pool of cells.^{212,349}

Although patients with plasma HIV-1 RNA levels below the limit of detection by routine clinical tests are considered to have “undetectable” viral loads, residual viremia (1–50 copies/mL) can be detected in nearly all patients when sufficiently sensitive methods are applied.²⁹⁶ Whether residual viremia reflects ongoing rounds of HIV replication, release of virus from long-lived productively infected cells or is due to activation of latently infected cells remains an area of controversy. The absence of viral evolution over time in subjects with detectable residual viremia and the inability to suppress residual viremia through intensification of ART by additional antiretroviral drugs argue against ongoing replication as a source of this virus.^{19,101,130,263} Some patients experience transient episodes of detectable plasma viremia (*blips*). In most studies, the occurrence of blips has not been associated with emergence of drug resistance or an increased risk of treatment failure.^{284,285} Mathematic modeling of the frequency of these blips suggests that they represent stochastic

bursts of replication, perhaps caused by intercurrent episodes of immune activation.^{100,303}

The rapid decline in plasma HIV-1 RNA is accompanied by a similarly brisk increase in CD4 T lymphocytes in most patients. On average, the CD4 cell count increases by 50 to 100 cells/mm³ in the first 4 weeks of therapy, followed by a more gradual, but steady, increase thereafter.²²⁸ Most of this initial increase in CD4 cell counts is thought to be the result of redistribution of memory CD4 T cells from lymphoid tissues into the peripheral blood.²⁹⁴ The subsequent slower increase is attributed, in turn, to the gradual increase in naïve CD4 T cells that is thought to represent production of naïve CD4 T cells.^{16,72,431} By the end of the first year of therapy, total CD4 cell counts increase by an average of 175 cells/mm³.^{129,242,410} Patients remaining on antiretroviral therapy over 7 years experience a CD4 count increase of 300 to 600 cells/mm³, depending on the CD4 count at the time of ART initiation.²⁴² Patients with incomplete suppression of plasma viremia also show significant increases in CD4 cell counts, but the magnitude of this increase is blunted compared with patients with complete viral suppression.^{204,205,391}

Viral suppression reduces generalized immune activation, as judged by the number or percentage of CD38+DR+ CD4 and CD8 cells.²²⁸ The proportion of activated cells remains greater, however, than that found in seronegative controls.^{193,375} Higher levels of immune activation are associated with lower levels of CD4 cell restoration on ART.¹⁹³ Reconstitution of the follicular DC network in lymphoid tissues can occur over time,⁴³² but central memory T cells (Tcm) do not appear to be reconstituted by successful ART.¹⁰⁷

The numeric increase in CD4 T cells is accompanied by laboratory and clinical evidence of reconstitution in pathogen-specific immunity. Proliferative responses to recall antigens such as *Candida albicans* and CMV can be demonstrated after 12 to 48 weeks of therapy.^{16,72,228,289,321} Prophylactic therapy to prevent new or recurrent episodes of *P. jirovecii* pneumonia,^{123,124,216} disseminated *Mycobacterium avium* complex infection,^{2,83} histoplasmosis,¹⁴⁴ and CMV retinitis^{247,399} can be discontinued safely in patients who have shown a satisfactory virologic and immunologic response to therapy. By contrast, lymphocyte proliferative responses to HIV antigens remains limited,^{16,72} although some studies have shown improvements in HIV-specific immunity by enzyme-linked immunospot (ELISPOT) assay or intracellular cytokine staining.^{35,321}

Immune reconstitution can be accompanied by a pathologic inflammatory response to previously treated or subclinical opportunistic infections. The immune reconstitution inflammatory syndrome (IRIS) occurs in up to one third of patients beginning ART, and is best described in association with CMV retinitis, disseminated *Mycobacterium tuberculosis*, or *M. avium* complex infection, and cryptococcal meningitis.^{44,329,367,368} Patients with IRIS are more likely to have started an initial ART regimen soon after diagnosis of an opportunistic infection, a low CD4 count below 50 cells/mm³, and to have a more rapid decrease in plasma HIV-1 RNA levels.^{279,368} Management includes continuation of ART, treatment of the associated opportunistic infection, and a brief course of steroids if the extent of inflammation risks significant end-organ damage or is life-threatening.¹⁷⁴

Drug Toxicity

A wide range of toxicities of varying severity has been described. In the case of the NRTIs, the more serious include anemia and neutropenia,³³⁷ peripheral neuropathy (stavudine [d4T], didanosine [ddI], zalcitabine [ddC]),^{30,114,276} pancreatitis (ddI and ddC),¹⁴⁸ and life-threatening lactic acidosis.^{59,243} Severe peripheral lipodystrophy has been associated with use of d4T, ddI, and zidovudine (ZDV), most likely caused by inhibition of mitochondrial DNA polymerase γ .^{50,199} As a result, these drugs are no longer recommended as first-line agents, although they continue to be used in resource-limited settings because of their low cost. Fatal hypersensitivity reactions can occur with abacavir in patients carrying the HLA B*5701 allele.^{172,248,255,316} Abacavir may also contribute to an increased risk of cardiovascular disease, although this finding remains controversial.^{78,335,351,427} Although tenofovir disoproxil fumarate (TDF) generally is well tolerated, uncertainty over possible long-term effects on bone metabolism limits its use in pregnancy and young children.⁵³ Similarly, concerns over potential nephrotoxicity have limited TDF use in patients with impaired renal function.^{200,214}

Use of nevirapine and efavirenz can be complicated by rash and hepatotoxicity. In the case of nevirapine, rash may be

severe (Stevens-Johnson syndrome).³²⁰ Life-threatening hypersensitivity hepatitis can occur with nevirapine, particularly in women with CD4+ T-cell counts greater than 250/mm³.^{3,353} CNS side-effects are a common cause of treatment discontinuation with efavirenz,⁶⁶ and concerns over teratogenicity restrict its use in pregnant women and women of childbearing age.⁹³

Gastrointestinal intolerance, hepatotoxicity, and hyperlipidemia are the most frequent dose-limiting toxicities associated with the protease inhibitors. The incidence of hepatotoxicity may be significantly increased among HCV co-infected patients.³⁸⁸ In addition, several drugs in this class significantly impair insulin sensitivity, possibly by an inhibitory effect on the glucose transporter GLUT4.²⁸¹ The combination of insulin resistance and hyperlipidemia can increase the risk of cardiovascular disease among patients receiving certain protease inhibitors.¹²² Hyperbilirubinemia, nephrolithiasis, and rash are additional concerns with certain members of this class. Use of the fusion inhibitor enfuvirtide (ENF), which requires subcutaneous injection, leads to development of painful subcutaneous nodules that limit long-term acceptability of this drug.²⁷⁰

When a change in therapy is prompted by drug toxicity, an alternative agent should be substituted for the offending drug without interrupting treatment. When toxicity is sufficiently severe to require suspension of dosing, all drugs in a regimen should be discontinued to avoid exposure of the virus to a partially suppressive regimen, which can result in selection of drug resistance (see below).

Treatment Failure

Numerous factors contribute to the failure of highly active antiretroviral therapy (HAART), including poor adherence (because of the complexity or poor tolerability of certain regimens)^{183,425}; pharmacologic factors, including drug–drug interactions that impair absorption or accelerate clearance²⁸²; host factors (e.g., low CD4 cell count at the start of treatment and HLA haplotype)^{5,179,315}; drug resistance acquired by transmission of a resistant isolate or selected by previous suboptimal therapy²³⁸; and preexisting drug-resistant minority variants.²³³ Each of these factors leads to incomplete suppression of viral replication, which in turn, leads to selection of drug-resistant variants.

The definition of treatment failure depends on where in the course of treatment an individual patient stands. For patients on a first or second regimen, treatment failure usually is defined as confirmed evidence of detectable viremia after an initial virologic response, or failure to achieve a response. Prompt switching to a new potent regimen is advised to reestablish virologic suppression, prevent emergence of drug resistance, and preserve future treatment options.^{192,283} Although many clinicians do not alter therapy unless the level of viremia exceeds 1,000 to 5,000 copies/mL, persistent low levels of detectable viremia can be associated with accumulation of drug resistance mutations.²⁸³

For patients with more extensive treatment histories, the situation is more complex. By this point, most patients already will have been exposed to all three classes of antiretroviral agents and may have developed resistance to at least one agent within each drug class. Therefore, the presence of detectable plasma HIV-1 RNA is less useful as a marker of treatment failure. In this situation, symptomatic evidence of treatment failure can include increasing fatigue, malaise, and night sweats; objective

evidence includes weight loss, a rising viral load, falling CD4 cell count, and occurrence of new, recurrent, or worsening AIDS-related opportunistic infections.

Even when complete virologic suppression cannot be achieved, ART continues to provide clinical benefits. Studies show that mean CD4 cell counts remain above pretherapy levels through 96 weeks of follow-up in patients experiencing virologic failure of a protease inhibitor regimen.⁹⁵ Maintenance of stable CD4 cell counts depends on continued administration of ART, even in patients with apparent virologic failure of their regimens.⁹⁶ An analysis of data pooled from 13 cohorts in Europe, North America, and Australia showed the continuing immunologic and clinical benefits of ART despite virologic failure.²²⁷ Those with plasma HIV-1 RNA levels above 10,000 copies/mL and CD4 cell counts below 200 cells/ μ L were at greatest risk of disease progression. Within each viral load and CD4 count stratum, the risk of disease progression was significantly lower for those who continued on ART despite virologic failure, confirming the persistent benefit of treatment in the setting of ongoing virus replication and presumed drug resistance.

Drug Resistance

As discussed above, the high error rate of HIV-1 RT and rapid turnover of the virus population contribute to the generation of extensive genetic variation in the HIV-1 quasi-species. These factors provide a mechanism for rapid emergence of drug resistance in the setting of partially effective ART. Resistance emerges at a rate proportionate to the frequency of preexisting variants and their relative growth advantage in the presence of drug.⁶⁸ Support for this model is provided by observations from monotherapy studies with different classes of antiretroviral drugs. For example, resistance to nevirapine and lamivudine emerges within weeks of initiating monotherapy because of point mutations that result in a thousand-fold reduction in drug activity.^{338,363} By contrast, resistance to drugs such as didanosine and tenofovir emerges slowly.^{222,252} In the case of zidovudine and most protease inhibitors, high-level resistance occurs as a consequence of the accumulation of multiple mutations over time.^{37,275} Given the extensive array of mutations implicated in resistance to various classes of antiretroviral drugs, a detailed discussion of resistance to individual drugs is beyond the scope of this chapter. The reader is referred instead to excellent reviews of this subject^{29,65,197} and to the several web sites that maintain a comprehensive listing of HIV-1 drug resistance data (www.hiv.lanl.gov; <http://hivdb.stanford.edu>; www.iasusa.org).

Several studies document the high prevalence of antiretroviral drug resistance in the developed world, and the rising incidence of transmission of drug-resistant virus.²³⁸ Data from the CDC show the prevalence of antiretroviral drug resistance to be approximately 15% among persons newly diagnosed with HIV-1 infection; resistance to drugs from two or more drug classes was found in 3% to 4%.^{140,414} A cohort study conducted in London showed the risk of accumulating at least one major drug resistance mutation was 27% by 6 years; the risk of mutations associated with resistance to drugs from at least two of the three main drug classes was 20% over the same period.³¹⁴

The clinical significance of antiretroviral drug resistance was demonstrated not long after the introduction of ZDV and ddI by studies that showed accelerated immunologic decline and disease progression in patients receiving nucleoside analogs to which their viruses had become resistant.^{88,191,222} As was

discussed, studies show the relationship between resistance to PI-based HAART regimens and clinical progression is more complex.^{95,96} Drug resistance comes at a cost to the virus in terms of replication capacity. Diminished replication capacity and residual activity of some drugs against resistant viruses may account for persisting reductions in AIDS incidence and AIDS-related mortality in the developed world despite the increasing prevalence of antiretroviral drug resistance.

Resistance to antiretroviral agents can be assessed by genotypic and phenotypic assays. These tests are an important tool for management decisions related to therapy initiation or regimen modification. Properly used, they can lead to improved virologic outcomes for patients infected with HIV-1.

Treatment as Prevention

Evidence that the risk of HIV-1 transmission correlates with viral load in the source patient leads naturally to the hypothesis that decreasing circulating levels of HIV-1 by effective antiretroviral therapy will reduce transmission.^{147,195,325,381} This hypothesis is supported by the successful use of ART to prevent perinatal and breast-milk transmission of HIV-1 from infected mothers to their infants,^{73,365} and by observational studies among HIV-1 discordant couples that show a substantially reduced risk of HIV transmission when the infected partner is receiving ART.^{13,334} These observational data have been confirmed in a randomized trial that showed a 96% reduction in the risk of sexual transmission of HIV by the group randomized to receive ART.⁷⁰ Although implementing public health policies based on these results remains an enormous challenge, the data show clearly the possibility for effective control of the HIV-1 pandemic given sufficient resources and political will.

Prospects for HIV Eradication

As discussed earlier in this chapter, the establishment of a reservoir of latently infected, resting CD4 lymphocytes results in the lifelong persistence of HIV-1 infection. Attempts to purge the reservoir by activating resting cells have thus far proved unsuccessful.³²⁴ Similarly, a report that valproic acid reduced the number of latently infected cells by inhibiting histone deacetylase (HDAC) was not confirmed by subsequent work.^{14,229,371} The effect of selective HDAC inhibitors such as members of the suberoylanilide hydroxamic acid (SAHA) class of molecules (e.g., vorinostat) on the HIV reservoir is an area of intensive study, including preliminary human trials.²⁵⁹ The report that HIV-1 is no longer detectable in an infected patient 3 years after receipt of an allogeneic bone marrow transplantation for acute myelogenous leukemia from a donor homozygous for the *ccr5* Δ 32 mutation has reinvigorated the search for potential cures for HIV-1 infection.^{69,182}

HIV VACCINES

Vaccines are arguably the most powerful medical intervention for preventing virus infections. Despite the obvious need, and years of intense research, the development of an effective vaccine against HIV has been elusive. Although many approaches have been tried, only four basic vaccine platforms have shown adequate promise to warrant large scale efficacy testing. Initial efforts were directed at using recombinant envelope proteins to stimulate antibodies to block infection. Although these

vaccines did stimulate envelope binding antibodies, they failed to induce antibodies capable of neutralizing strains of HIV other than easy to neutralize laboratory-grown viruses, and the trials failed to demonstrate protection against HIV infection.^{120,318} The inability to induce broadly neutralizing antibodies through vaccination has continued to be a vexing problem, and is probably related to a number of factors, including sequence variability, especially within exterior loops of the envelope that are highly immunogenic but that can easily mutate to avoid recognition, and the heavy glycosylation of the envelope.³⁸² The recent isolation of broadly neutralizing antibodies from HIV-infected subjects, and the identification of the antigenic target of these antibodies on the HIV envelope, have raised hope that an immunogen can be developed that targets conserved sites of vulnerability on the HIV envelope.^{297,408,409,428}

Because of the failure of early vaccines to protect against HIV acquisition, a subsequent approach was to stimulate broad HIV-specific CD8 T-cell responses in the hope that these responses would at least control viral replication in those who became infected with HIV, thereby limiting the impact of the infection upon the vaccinated individual, and potentially influencing the subsequent transmission of HIV to other individuals. A trial of a recombinant adenovirus-based vaccine was performed, and although it did stimulate strong CD8 T-cell responses, it failed to protect vaccinees from infection or affect their viral loads, and actually increased HIV acquisition within subjects with pre-existing immunity to the vaccine vector (adenovirus type 5).^{46,262} Although the mechanism underlying the increase in acquisition is still under investigation, the failure of this trial has severely dampened enthusiasm for T-cell-based vaccine strategies.

On a more optimistic note, vaccine that combined a pox-based vector and recombinant envelope protein did show moderate (31%) protection against HIV acquisition in a low-risk predominantly heterosexual population.³³³ This vaccine did not stimulate strong neutralizing antibody responses, and virtually no CD8 T-cell responses, so the exact mechanism of protection afforded by the vaccine is currently unknown but is certainly the subject of intense investigation. Further studies of similar vaccines are being planned. Finally, a fourth vaccine platform is being evaluated in an efficacy trial. This vaccine is based upon adenovirus type 5, but includes the HIV envelope protein and induces envelope-specific antibodies.^{190,211} The fact that an efficacy signal has been seen with a vaccine has infused optimism into the vaccine field, though it will still be years before a licensed vaccine could be available.

Other Prevention Strategies

Sexual behavioral change can clearly diminish the risk of becoming infected, as has been shown in Zimbabwe with a reduction in casual sex and a delay in sexual debut accounting for the greatest differences,¹⁵¹ and which has also been suggested for Uganda. In addition, knowledge of the mechanisms of transmission (discussed previously) has led to other nonvaccine interventions aimed at reducing transmission. It was long assumed that the mucosa of the male foreskin was a site of HIV acquisition in men, a contention supported by epidemiologic data. This was confirmed when an initial trial of more than 3,000 uncircumcised men who were randomized to be offered immediate circumcision or circumcision after a 21-month period of follow-up was stopped after an interim analysis at 18 months revealed that circumcision conferred 60% protection from HIV infection.¹⁷

These findings have been confirmed in two subsequent randomized clinical trials,^{20,149} and efforts are ongoing to deploy circumcision to high-risk male populations.

Other efforts to provide both men and women with a means of protection from infection have focused on the development of topical microbicides. Most of these efforts have proven to be failures in field trials, with at least one actually increasing the risk of HIV transmission.^{277,401} Of interest, a topical antiretroviral microbicide was effective when used intravaginally in women, but failed when given orally, potentially highlighting the importance of the local environment when designing strategies to block HIV transmission.^{1,384} The ultimate goal of prevention strategies is to have multiple options for diverse populations, including vaccines, barriers, and oral and topical prophylaxis.

HISTORY

Use of the term “slow virus infections” and identification of the first lentivirus is generally credited to Sigurdsson et al.^{314,315–316} in Iceland. Twenty karakul sheep that were imported from Germany to Iceland in 1933 were responsible for the transmission of a chronic disease and death in massive numbers of Icelandic sheep over subsequent years. More than 100,000 Icelandic sheep died of the disease in the decades that followed. Sigurdsson et al.^{314,315–316} not only described the disease but also demonstrated that it was due to a transmissible agent. They used the term slow virus infections to refer to this disease as well as to what is now known as scrapie.³¹³ The term has since been used to describe a wide variety of nonacute, persisting viral infections. In 1960, Sigurdsson et al.³¹⁷ described the cultivation of the transmissible agent in tissue culture, and Guðnadóttir and Pálsson¹¹⁵ were able to reproduce the disease with the culture-grown virus. The diseases in the sheep

were called *maedi* (Icelandic for dyspnea, that is, a lung disease resulting in difficulty breathing) and *visna* (Icelandic for a state of progressive apathy, a “fading away,” resulting from brain disease). Both disease states result from the same virus, now referred to as maedi/visna virus (MVV). MVV and related viruses are called lentiviruses, derived from the Latin *lentus* for slow. Approximately 600,000 sheep were slaughtered in Iceland in 1965 to eradicate MVV from the island.

The maedi/visna disease in Icelandic sheep, although the first specifically shown to be caused by a defined lentivirus, is probably not the first description of a lentiviral disease in the literature. Vallée and Carré described in 1904 the infectious nature of the disease equine infectious anemia,³⁴³ which is now known to be caused by a lentivirus (EIAV). Even for MVV, a chronic, progressive interstitial pneumonia had been described in South African sheep in 1915 and in Montana sheep in 1923.²¹³ Work with EIAV was largely on a parallel track with that of MVV, and the first description of EIAV cultivation appeared in 1961.¹⁷² Only subsequently were EIAV and MVV shown to belong to the same lentivirus subfamily of retroviruses on the basis of morphologic criteria.^{111,253,363}

The scenario of disease outbreak in a susceptible population leading to the identification of a new lentivirus has repeated itself dramatically on several occasions in more recent history. In 1964, an emerging infectious disease was first detected in Bali cattle in the Jembrana district of Bali.^{272,321} Bali cattle are the domesticated form of the wild banteng (*Bos javanicus*). Within 12 months, 26,000 of the 300,000 cattle on the island died of the disease. The cause of the disease was subsequently traced to a bovine lentivirus now called Jembrana disease virus (JDV), a distinct variant of bovine immunodeficiency virus (BIV).^{36,162} Bali cattle are particularly sensitive to disease caused by this virus, whereas other species are resistant.^{322,323,366} Outbreaks of immunodeficiency disease and lymphoma in captive colonies of macaque monkeys (Asian Old World primates) were subsequently traced to the introduction of a simian lentivirus or lentiviruses from African monkeys.^{18,61,201,208} Simian immunodeficiency viruses (SIVs) naturally infect African nonhuman primates without apparent disease, but Asian macaques appear to harbor no such virus naturally. Even the origins of human immunodeficiency virus (HIV) in people have followed a similar pattern. HIV-2 in people in western Africa clearly originated from SIV of sooty mangabey monkeys.^{41,70,99,129,184,214} The natural habitat of sooty mangabey monkeys is the same geographic region in western Africa where HIV-2 is endemic, and SIV from sooty mangabey monkeys groups phylogenetically with HIV-2 distinct from other lineages of primate lentiviruses. Sooty mangabey monkeys are naturally infected with SIV at high frequency without apparent disease. The origins

TABLE 51.1 Known Lentiviruses

Species	Virus	Year that cultivation was first published and reference
Sheep/goats	Maedi/Visna virus; caprine arthritis encephalitis virus	1960 (317)
Horses	Equine infectious anemia virus	1961 (172)
Cattle	Bovine immunodeficiency virus; Jembrana disease virus	1972 (345)
Humans	Human immunodeficiency virus	1983 (13)
Monkeys	Simian immunodeficiency virus	1985 (61)
Cats	Feline immunodeficiency virus	1987 (256)

of HIV-1 in central Africa have similarly been traced to the chimpanzee *Pan troglodytes*.^{51,97,305} These examples illustrate the importance of studying animal viruses even when they are not apparently associated with any disease.

The earliest descriptions of the isolation of HIV and its association with acquired immunodeficiency syndrome (AIDS) did not appreciate that the virus was a lentivirus.^{13,270} Only subsequently, through more careful examination of electron micrographs and through sequence analysis, did this become clear.^{112,227} At the time, study of lentiviruses was an obscure discipline with which many scientists were not familiar.

From a historical perspective, MVV³¹⁷ and EIAV¹⁷² were discovered, isolated, and characterized long before the discovery of HIV; the field has retained use of the original designations for these viruses. Lentivirus groupings identified after the discovery of HIV have used a nomenclature similar to that for HIV (i.e., “immunodeficiency virus”). BIV, originally isolated from a cow with a chronic disease by Van Der Maaten et al. in 1972,³⁴⁵ received little attention until after the discovery of HIV. Subsequent to the discovery of HIV, lentiviruses were isolated from monkeys and cats (Table 51.1). Although discovery of MVV, EIAV, and BIV predates that of HIV, HIV has received such intense scrutiny that much more is known about it than all other lentiviruses in terms of the level of detailed knowledge. New information about other lentiviruses is thus usually compared with what is known for HIV.

INFECTIOUS AGENT

Overview of General Properties

Related lentiviruses have been isolated from sheep, goats, horses, cattle, cats, monkeys, and humans (Table 51.1). Genetic analysis of the virus from goats (caprine arthritis encephalitis virus; CAEV) indicates that it clusters closely with MVV,³⁴² therefore is placed in a single grouping with MVV. Based on host species and the genetic analyses described in more detail later in this chapter (Genome Organization and Composition section), five discrete evolutionary groupings of lentiviruses are generally recognized (Fig. 51.1A). It is likely that more remain to be identified. It is important to realize that even within a single grouping, discrete subgroupings based on host species, geography, and genetic distance can be defined. For example,

among the nonhuman primate lentiviruses, distinctly different subgroupings exist for the SIVs from African green monkeys, sooty mangabey monkeys, Sykes' monkeys, and L'hoesti monkeys (Fig. 51.1B). Even among African green monkeys, which inhabit virtually all of sub-Saharan Africa, discrete genetic sub-subgroupings of SIVagm can be defined that correlate with subspecies and natural geographic habitat (Table 51.2 and Fig. 51.1B).

All lentiviruses have a common morphogenesis and morphology that distinguish them from other subgroups of retroviruses (see Chapter 47). Lentiviruses bud from the plasma membrane without a preformed nucleoid, and mature particles typically have a conical or rod-shaped nucleoid (Fig. 51.2). Classification into the lentivirus subgroup by morphologic criteria alone is entirely consistent with phylogenetic analysis of *pol* gene sequences. Viruses classified as lentiviruses have *pol* gene sequences more closely related to one another than to other retroviruses, and all have the characteristic morphogenesis/morphology. All lentiviruses have a propensity to replicate in macrophages, and all are associated with a chronic progressive disease course in susceptible hosts. The primate lentiviruses have acquired use of CD4 as one of two receptors used sequentially by virus for entry into cells (Table 51.3). FIV has been shown to use an analogous two-receptor sequential mechanism for entry. However, lentiviruses from nonprimates, including FIV, do not use CD4 as a receptor for entry. The chronic disease induced by the primate lentiviruses in susceptible hosts has an immunodeficiency component presumably because of the targeting of CD4⁺ lymphocytes by use of CD4 as a receptor. All lentiviruses have a number of auxiliary genes (i.e., genes in addition to *gag*, *pol*, and *env* not found in other, simpler retroviruses). Major distinguishing properties are summarized in Table 51.3.

GENOME ORGANIZATION AND COMPOSITION

Widespread availability of DNA sequencing capabilities has greatly facilitated our understanding of phylogenetic relationships and the gene products of lentiviruses. Based on sequence analysis, five discrete groupings of lentiviruses are now recognized (see Fig. 51.1A). It is likely that other groupings remain to be discovered. Extensive diversity exists even within a grouping. For example, among the SIVs, distinct subgroups have been defined from the African green monkey, sooty mangabey monkey, L'hoesti monkey, and Sykes' monkey (see Fig. 51.1B and Table 51.2). In all, 14 discrete phylogenetic lineages of primate lentiviruses have so far been defined (Fig. 51.1B and Table 51.2). Of the 69 species known to inhabit sub-Saharan Africa, SIV infection has been demonstrated in 40 of them, partial SIV sequence information is available from 32 species, and complete SIV genome sequences are available from 20 species.¹ Since some species have not yet been surveyed, additional SIV lineages may still remain to be discovered. Extensive diversity has also been observed for FIV in wild and captive cat species.^{34,336} Even among the four subspecies of African green monkeys (vervet, grivet, tantalus, and sabeus), discrete sub-subgroupings of SIVagm have been defined (Table 51.2). These four subspecies naturally inhabit distinct or sometimes partially overlapping habitats that cover almost all of sub-Saharan Africa. JDV represents a distinct subgroup relative to the original BIV isolate, analogous to SIVagm versus SIVsm.³⁶

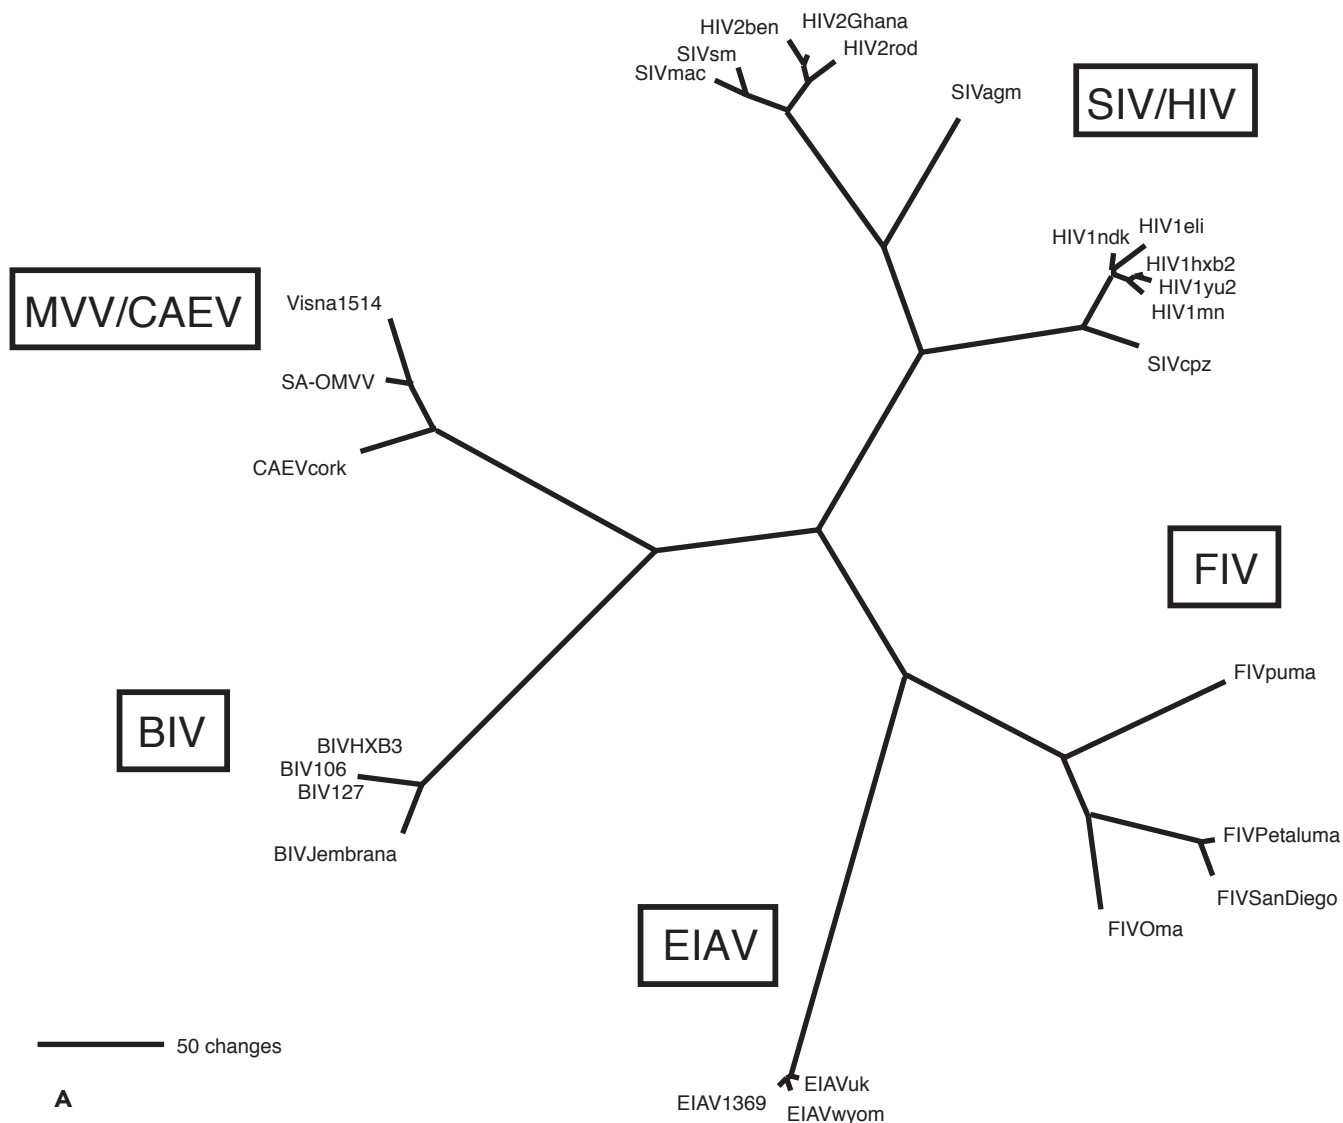

FIGURE 51.1. Phylogeny of the lentiviruses. A: Five discrete evolutionary groupings of lentiviruses. The unrooted tree depicts the phylogenetic relationships among the five recognized groups of lentiviruses. The tree is based on a 470-amino-acid alignment of reverse transcriptase sequences from representative members of each group, including the bovine (BIV, Jembrana), equine (EIAV), feline (FIV), ovine/caprine (visna, CAEV) and primate (SIV, HIV) lentiviruses. Maximum parsimony (shown) and neighbor-joining (not shown) analyses give trees of nearly identical topology. Branch lengths are proportional to the number of amino acid replacements. (*continued*)

The *pol* gene generally exhibits the greatest degree of sequence conservation. Thus, *pol* gene sequences are often used for the comparison of lentiviruses from different groups, subgroups, or sub-subgroups. Sequences from one subgroup of SIV (e.g., SIVsm) will typically exhibit only 55% to 60% identity in *pol* at the amino acid level when compared with sequences from another SIV subgroup (e.g., SIVagm). Diverse members within a subgroup may exhibit as little as 75% to 80% amino acid identity in *pol*, but the number is typically much higher. When different groups of lentiviruses are compared—for example, MVV with SIV—amino acid identity in *pol* is typically 35% or less. Relatedness in other genes is even less than that. Nonetheless, these lentiviral sequences are clearly more closely related to one another than to other retroviruses, justifying their classifica-

tion as lentiviruses on the basis of morphogenesis/morphology and biologic properties.

All known lentiviruses have at least three genes in addition to the standard *gag*, *pol*, and *env* genes that all replication-competent retroviruses possess (Tables 51.4 and 51.5, and Fig. 51.3). These extra genes likely contribute to a more complex life cycle for the lentiviruses, which includes persistent viral replication and strategies for immune evasion discussed in more detail later in this chapter (Immune Responses and Persistence section). A *rev* gene that encodes a protein responsible for controlling the relative level of full-length vs. multiply spliced viral messenger RNAs (mRNAs) is present in all lentiviruses, along with a downstream nucleotide sequence referred to as the Rev-Response Element (RRE). Interestingly, neither the sequence

nor location of the RRE is conserved, but the function appears to be the same in all lentiviruses. A *vif* gene, whose main role appears to be to counteract the cellular restriction factor APOBEC, is consistently present in five of the six lentivirus groupings. EIAV, however, stands alone in apparently lacking a *vif* gene. Whether another protein may contribute *vif* function for EIAV remains to be determined. A *nef* gene is found at the 3' end of all primate lentiviruses (Table 51.5). None of the nonprimate lentiviruses contains a *nef* gene. However, cells infected with EIAV and BIV have been found to make spliced RNAs that predict protein products called Ttm and Tmx that correspond to the carboxy-terminal portion of transmembrane protein (TM).^{17,110} Whether these represent evolutionary precursors to *nef* or perform functions similar to those of *nef* is yet to be determined. All lentiviruses except FIV contain an unusually long (>120 amino acids) cytoplasmic domain of TM. In the intergenic region between *vif* and *env*, a number of other genes can be present, particularly in the primate lentiviruses. A *vpr* gene is present in this region in all primate lentiviruses that have been examined. The SIVsm/SIVmac/HIV-2, SIVrcm and SIVmnd2 subgroups of viruses contain an additional homolog of *vpr* called *vpx* (Table 51.5). The nonprimate lentiviruses also contain a gene between the *vif* and *env* genes with varied roles. BIV encodes a Tat protein from this location that acts

on a downstream Tar element similar to the primate lentiviruses.¹⁹⁷ A small protein is also encoded from this region of the ruminant lentiviruses that was originally thought to be a transcriptional transactivator but which may actually be more vpr-like in activity.³⁵⁴ Likewise, a small protein encoded in a similar region by FIV, termed OrfA, was originally thought to be a transactivator, but has recently been shown to downregulate CD134 receptor expression on the infected cell, similar to CD4 downregulation by HIV and SIV Nef.¹³³ Only two of the 14 groups of primate lentiviruses that have been analyzed to date consistently have a gene called *vpu*: HIV-1/SIVcpz and SIVgsn/SIVmon/SIVmus (Table 51.5). SIVden from a pet Dent's Mona monkey (*Cercopithecus mona denti*) was found to contain a *vpu* gene, although the virus clustered phylogenetically more closely to the SIV from DeBrazza monkeys, SIVdeb.⁶²

Except for BIV, nonprimate lentiviruses encode a deoxyuridine triphosphatase (dUTPase) activity from a distinct open reading frame located within the *pol* gene.⁸⁵ dUTPase converts dUTP to a precursor of dTTP, thus keeping the concentration of dUTP in the cell at low levels. By doing so, dUTPase indirectly prevents misincorporation of uracil into viral DNA, ultimately reducing mutagenic G>A transitions. dUTPase is particularly relevant for virus replication in nondividing cells like macrophages in which endogenous dUTPase levels are low. Curiously, these dUTPase coding sequences are absent in the primate lentiviruses but present in the type D beta retroviruses. The explanation for this variable presence of dUTPase is not entirely clear. The type D retroviruses and lentiviruses may possibly have diverged from a common ancestor that possessed such a dUTPase reading frame, and this reading frame may then have been lost in the evolution of primate lentiviruses from the more primitive ones. The type D retroviruses and lentiviruses do share a common morphology of the mature particles (i.e., a cylindrical, rod-shaped, or conical nucleoid), which also may suggest some commonality. Alternatively, the presence of a dUTPase reading frame in nonprimate lentiviruses and in type D retroviruses could be an example of convergent evolution, with two distinct lineages acquiring these sequences independently by gene capture or by sequence duplication and point mutation. Another possibility is that one viral lineage may have acquired dUTPase sequences from the other viral

TABLE 51.5 Auxiliary Genes Primate Lentiviruses

	SIVsm/ SIVmac/HIV-2	SIVagm	SIVsyk	SIVsun/ SIVhoesti	HIV- 1/SIVcpz	SIVgsn/ SIVmon/ SIVmus	SIVrcm
<i>vif</i>	+	+	+	+	+	+	+
<i>vpu</i>	—	—	—	—	+	+	—
<i>vpr</i>	+	+	+	+	+	+	+

<i>tat</i>	+	+	+	+	+	+	+
<i>rev</i>	+	+	+	+	+	+	+
<i>nef</i>	+	+	+	+	+	+	+

Note: SIVmnd2 has a *vpx* gene, but SIVmnd1 does not. SIVden from a pet Dent's Mona monkey (*Cercopithecus mona denti*) has a *vpu* gene, although it clusters more closely to the SIV from DeBrazza monkeys, SIVdeb. SIVdeb has a *vpr* gene, but no *vpx* or *vpu* genes.

lineage by a recombination or capture event.¹² The presence of a dUTPase in the endogenous SIV found in the germline of the prosimian lemur¹⁰⁷ supports the notion that dUTPase was lost in the evolution of nonprimate to primate lentiviruses. The loss of dUTPase in the evolution from nonprimate to primate lentiviruses could relate at least in part to the predominant replication of nonprimate lentiviruses in cells with little potential to divide (macrophages) where endogenous dUTPase levels are low versus the predominant replication of primate lentiviruses in cells with much greater potential to divide (lymphocytes) in which high levels of endogenous dUTPase prevail. Primate lentiviruses incorporate uracil DNA glycosylase into virions through its binding to *vpr*,²⁰⁹ thus facilitating excision and subsequent repair of misincorporated uracil in newly synthesized viral DNA. The presence of the dUTPase or uracil DNA glycosylase in virions serves to reduce the mutation frequency in reverse transcription products.

PROPAGATION

Propagation and Assay in Cell Culture

Primary isolates from all lentivirus groupings can be grown in normal macrophage cultures of the host species. Other types of cells may be more typically used for propagating the individual viruses in routine cell culture. The types of cells that can be used vary with the virus (Table 51.6) and almost certainly relate to the kinds of receptor that can be used in most cases. Isolates also can be adapted to replicate on particular cell substrates. Examples of the latter include growth of FIV on Crandell feline kidney cells and growth of SIVs and HIVs on human tumor T-cell lines (Table 51.6). It is important to note that the strong selective forces that allow replication in particular cells may make research convenient but may lead to results atypical of natural infection.

Host Range

The lentiviruses are typically restricted in their host range, but both natural and experimental cross-species infections have been documented. SIVs naturally infect a variety of African nonhuman primates, but a single example of natural infection of Asian Old World monkeys has never been documented. The SIVs from sooty mangabey monkeys and African green monkeys, when introduced into macaque monkeys (Asian Old World primates), can infect them and cause an AIDS-like disease.^{94,127,233} In fact, the SIV of sooty mangabey monkeys

was accidentally introduced into macaque monkeys in captive United States colonies on at least one occasion and disseminated unknowingly into other macaques for more than a decade before it was discovered and eliminated.^{8,59,208} At least one clear case of laboratory-acquired infection of a human with SIVmac has been documented.^{166,325}

Cross-species transmission of SIV to baboons in the wild has been documented. Baboons do not appear to harbor their own SIV naturally. Of 279 baboon sera taken from native habitats in Tanzania and Ethiopia, 277 were negative for the presence of antibodies to SIV. However, two gave strong reactivity to SIVagm antigens.¹⁷³ One of these two was subsequently shown to harbor SIVagm sequences in stored plasma. The SIVagm sequences clustered with the vervet subtype, consistent with the known cohabitation of vervet monkeys in the same region where the baboon samples were taken.¹⁵¹ An SIVagm variant has similarly been detected in a chacma baboon of southern Africa.³⁴⁷ Baboons also can be infected experimentally with HIV-2.¹⁹⁸ Evidence for cross-species transmission of SIV from West African green monkeys (*Cercopithecus aethiops sabeus*) to patas monkeys (*Erythrocebus patas*) and to white-crowned mangabeys (*Cercocebus torquatus lunulatus*) has also been presented.^{20,334} Transmission of SIV or HIV to nonprimates has not been documented.

The origins of both HIV-2 and HIV-1 in humans are now generally believed to be from cross-species transmission. HIV-2 is endemic in western Africa and has only slowly made its way to other regions of the world. The SIV from sooty mangabey monkeys is closely related to HIV-2, has the same genome organization as HIV-2, and groups phylogenetically with HIV-2, distinct from the other 13 groups of primate lentiviruses (Fig. 51.1B). The native habitat of the sooty mangabey monkey is the coastal forest regions of western African, the same region where HIV-2 is endemic. Thus, strong circumstantial evidence involving both viral sequences and geographic colocalization link the monkey and human lentiviruses in western Africa.^{42,70,99,129} Similarly, of the four subspecies of chimpanzees, at least two (*Pan troglodytes troglodytes* and *Pan troglodytes schweinfurthii*) naturally harbor lentiviruses in the HIV-1/SIVcpz group.^{51,97,305} HIV-1s from the three divergent HIV-1 groupings M, N, and O are each more closely related to the *P. t. troglodytes* SIVcpz than to the *P. t. schweinfurthii* SIVcpz. HIV-1 groups N and O are largely restricted to west equatorial Africa where *P. t. troglodytes* are found.^{51,97} Although more work needs to be done on the lentiviruses naturally harbored by the four subspecies of chimpanzees, the evidence to date provides

TABLE 51.6 Cell Substrates for Growing Lentiviruses

Lentivirus group	Growth on Macrophages	Other cell types	Adaptation to growth
HIV-1	Yes	Stimulated, primary, human CD4 ⁺ lymphocytes	Human tumor T-cell lines
SIV	Yes	Stimulated, primary, monkey CD4 ⁺ lymphocytes	Human tumor T-cell lines
MVV/CAEV	Yes	Choroid plexus cells; primary synovial cells; endothelial cells	—
FIV	Yes	Primary, stimulated feline lymphocytes	Crandell feline kidney cells
EIAV	Yes	—	Fetal equine kidney; equine dermal
BIV	Yes	—	Bovine, rabbit, canine fibroblasts

FIGURE 51.4. Chimpanzee “Sagu” eating a leg of a red colobus monkey. (Photo by Sonja Metzger, Max-Planck-Institute for Evolutionary Anthropology. See Aghokeng et al (1) and Leendertz et al.¹⁸³ (Courtesy of the Centers for Disease Control and Prevention, Atlanta, Georgia.)

strong support for the introduction of a lentivirus from *P. t. troglodytes* (or possibly from gorilla,²³⁶) into the human population on three or more occasions for the origins of groups M, N, and O of HIV-1. Use of the hypodermic syringe, deforestation, massive migrations to urban centers in Africa, and vaccination campaigns have all been suggested as possible explanations for why these cross-species transmissions and disseminations have succeeded only recently in history.

Detailed sequence analyses have revealed that SIVcpz is more closely related to SIVgsn than to other SIVs in the 3′ half of its genome and is more closely related to SIVrcm in the 5′ half of its genome.¹¹ Furthermore, until recently, HIV-1/SIVcpz and SIVgsn/SIVmon/SIVmus were the only groups of primate lentiviruses with *vpu* genes. The natural range of the west-central African chimpanzee (*P. t. troglodytes*) overlaps that of both red-capped mangabeys and greater spot-nosed monkeys. In addition, chimpanzees are known to prey on and eat monkeys for food (Fig. 51.4). Thus, the origins of SIVcpz in chimpanzees may be connected directly or indirectly to greater spot-nosed monkeys and/or red-capped mangabeys. SIVden from *C. mona denti* has now also been found to contain a *vpu* gene, although overall it clusters more closely with the SIV from DeBrazza monkey, SIVdeb.⁶² Sorting out the origins of SIVcpz, and consequently HIV-1 in humans, is complicated by the sheer numbers of species likely to harbor phylogenetically distinct SIVs, the potential for cross-species transmission, and the potential for retroviral recombination events.³⁰⁵

Attempts to transmit HIV-1 experimentally to a variety of animal species have shown a restricted host range. HIV-1 is infectious for chimpanzees, and a chimpanzee-passaged HIV-1 has shown pathogenic potential.^{246,247} An early report described HIV-1 infection of pig-tail macaques (*Macaca nemestrina*),²

but this model has not proven sufficiently robust to date for general use.

The nonprimate lentiviruses are also restricted in their host range, limited to the same or closely related genera. BIV is a notable exception in that it has been reported to infect New Zealand white rabbits.²⁶⁴ Cross-species infections do occur, however. Cross-species infection of sheep from goats by the goat lentivirus has been observed,²⁶⁵ consistent with the high degree of genetic relatedness between the caprine arthritis-encephalitis virus (CAEV) of goats and the sheep lentivirus MVV. Studies have also shown that domestic cats can be infected by puma lentivirus (FIVpco) and by lion lentivirus (FIVple).^{349,350} No overt disease symptoms have been associated with the latter infections, but long-term studies have not been performed.

Restriction

Cellular proteins have been defined in recent years that directly interfere with different stages of virus replication. These proteins, termed restriction factors, constitute an important defense against lentivirus infection at the cellular level, collectively referred to as “intrinsic immunity.” There are presently three lentiviral restriction factors that have been extensively studied: APOBEC3G/F, TRIM5 α , and tetherin/BST-2, discovered in 2002,³⁰⁷ 2004,³²⁸ and 2008,^{238,344} respectively. Although their mechanisms of antiviral activity are diverse, they are linked to innate immunity through induction by type I and type II interferons. Lentiviruses have, in turn, evolved countermeasures to each of these restriction factors to facilitate persistent replication in their respective hosts. As a consequence of this ongoing evolutionary conflict, APOBEC3G/F, TRIM5 α , and tetherin have acquired species-specific differences that represent important host range determinants of lentiviral infection.^{222,291,292}

APOBEC3G and 3F are incorporated into virus particles in the absence of Vif and result in a producer cell-dependent block to virus infectivity.^{96,357} These cytidine deaminases introduce C-to-U mutations in minus-strand DNA during the process of reverse transcription, which are then copied into G-to-A transitions upon plus-strand DNA synthesis.^{119,377} APOBEC3G and 3F preferentially deaminate the 3' dC in CC and TC dinucleotides respectively.^{14,21,38,193,365} The antiviral activity of APOBEC3G and 3F is a direct result of the accumulation of extensive mutations in the proviral genome, a phenomenon known as hypermutation.^{120,182,206,383}

HIV, SIV, and other lentiviruses are resistant to the APOBEC proteins of their respective hosts by virtue of the ability of their Vif proteins to prevent APOBEC incorporation into virions. Vif does this by serving as an adaptor to recruit the cullin-5-elongin B/C-Rbx ubiquitin ligase complex to APOBEC3G and 3F, which leads to the polyubiquitylation and subsequent proteasomal degradation of these proteins in infected cells.^{49,211,306,378} By depleting cytosolic pools of APOBEC3G and 3F, Vif significantly reduces their encapsidation into virions.

The sensitivity of APOBEC3G to Vif-mediated degradation is often species specific.³¹⁸ HIV-1 Vif can degrade the APOBEC3G proteins of humans and chimpanzees, but not African green monkeys or rhesus macaques.²¹⁰ Similarly, SIV_{agm} Vif can degrade African green monkey APOBEC3G, but not human APOBEC3G.²¹⁰ This specificity is governed by a single amino acid difference at position 128 (aspartic acid in humans versus lysine in Old World monkeys) that is critical for binding to Vif.^{22,207,298} The failure of HIV-1 Vif to counteract the APOBEC3G proteins of Old World monkeys in part accounts for the inability of HIV-1 to replicate in these species. Likewise, the inability of SIV_{agm} Vif to counteract human APOBEC3G may pose a significant barrier to the zoonotic transmission of this group of primate lentiviruses to humans.

TRIM5 α imposes a post-entry block that represents a major host range determinant for lentiviruses as well as other types of retroviruses. This block occurs before reverse transcription and susceptibility/resistance is determined by sequences in the capsid protein.^{124,132,311} Evolutionary analyses have revealed that *TRIM5* has been co-evolving with retroviral pathogens for tens of millions of years, perhaps since the radiation of eutherian mammals.²⁹⁰ Homologs of the *TRIM5* gene have been found in the genomes of primates, cows, pigs, dogs, rabbits, rats, and mice,²⁹⁰ and anti-viral activity has been demonstrated for the TRIM5 α proteins of various species of Old and New World primates^{121,287,324} as well as for the related TRIM5 proteins of rabbits and cows.^{294,376} A common theme is that these TRIM5 proteins do not block infection by retroviral pathogens of their host, but exhibit variable patterns of restriction against retroviruses of other species.¹²¹ The underlying basis for this differential restriction is sequence variation in the B30.2 domain.^{190,235,294,368,375} One of the more peculiar twists in *TRIM5* evolution is the independent emergence of a TRIM5-cyclophilin A (TRIM5Cyp) fusion protein in at least two different primate lineages. Owl monkey cells exhibit a potent post-entry block to HIV-1 infection due to a TRIM5Cyp fusion protein resulting from the LINE-1-mediated retrotransposition of an open reading frame for *CypA* into the intron between exons 7 and 8 of *TRIM5*.^{243,293} A similar TRIM5 Cyp fusion was identified in Old World primate species of the macaque genus, including rhesus macaques, pig-tailed

macaques, and cynomolgous macaques.^{27,191,241,355,369} In this case, the CypA insertion occurred in the 3' UTR of *TRIM5* and is linked to a second mutation in the splice acceptor site of exon 7 favoring splicing of the mRNA transcript to the downstream open reading frame for CypA. Macaque TRIM5Cyp poorly restricts HIV-1, but does block infection by other lentiviruses, including SIV_{agm}, HIV-2 and FIV.^{355,369} The functional blocks to lentiviral infection imposed by these TRIM5Cyp proteins, which clearly represent distinct retrotransposition events, are believed to be the result of convergent evolution.

Sequence analyses have also revealed extensive *TRIM5* polymorphism in rhesus macaques and sooty mangabeys.²⁴⁰ Clusters of synonymous and nonsynonymous nucleotide substitutions were identified in regions of the gene coding for the CC and B30.2 domains with multiple alleles present at high frequencies in both species.²⁴⁰ Moreover, a number of specific polymorphisms were found in the *TRIM5* genes of both rhesus macaques and sooty mangabeys, despite an estimated divergence time of over 8 million years.²⁴⁰ Sequence variation in the B30.2 domains of these species' TRIM5 α proteins was also shown to result in the differential restriction of a number of lentiviruses, including HIV-1, HIV-2, FIV, and ELAV.^{240,368} These observations imply that balancing selection has acted over millions of years to preserve ancient TRIM5 α polymorphisms with functional diversity in their ability to block virus infection in Old World monkeys.

TRIM5 polymorphisms have been found to account for the highly variable course of infection for SIV_{sm}E543-3 in rhesus macaques. In contrast to SIV_{mac}239, which consistently results in high viral loads with minimal animal-to-animal variation, viral loads in SIV_{sm}E543-3-infected rhesus macaques are highly variable. Kirmaier et al. found that this variation is strongly associated with differences in *TRIM5* genotype.¹⁷⁰ The resurgence of SIV_{sm}E543-3 replication in animals with restrictive TRIM5 alleles was also associated with an arginine-to-serine change at position 97 in capsid (R₉₇S) corresponding to the residue present at this position in SIV_{mac}239.¹⁷⁰ Thus, while SIV_{mac}239 has had sufficient time to adapt to rhesus macaque TRIM5 protein, SIV_{sm}E543-3 evidently has not. These observations illustrate the influence of TRIM5 polymorphisms on the differential suppression of a virus that has not fully adapted to its host.

Efforts to determine the role of the HIV-1 Vpu protein in virus release led to the identification of tetherin (BST-2 or CD317) as an interferon-inducible host-cell factor that interferes with the detachment of virus particles from infected cells.^{237,238,344} Tetherin is a type II integral membrane protein with a topology that allows both ends of the molecule to be anchored in lipid membranes.¹⁷⁴ It has an N-terminal cytoplasmic domain, a transmembrane domain, an extracellular coiled-coil domain and a C-terminal glycosyl-phosphatidylinositol anchor.¹⁷⁴ Tetherin is upregulated in response to interferon and becomes incorporated into virus particles as they attempt to bud from the surface of infected cells.^{89,116,260} Captured virions are then internalized and routed for lysosomal degradation.^{226,260}

The primate lentiviruses have evolved at least three different viral gene products to overcome restriction by tetherin. Whereas HIV-1 Vpu and HIV-2 Env antagonize human tetherin,^{180,238,344} most SIVs, including members of the phylogenetically diverse SIVcpz, SIV_{agm}, and SIV_{smm} lineages, use Nef to counteract the tetherin proteins of their nonhuman primate

hosts.^{149,289,382} An exception are the SIVs of Old World monkeys that contain a *vpu* gene (SIVgsn, SIVmon, SIVmus and SIVden), which use Vpu rather than Nef to counteract the tetherin proteins of their respective hosts.²⁸⁹ Tetherin antagonism by HIV-1 Vpu depends upon a physical interaction between the membrane-spanning domains of Vpu and tetherin^{147,281} and in part on the recruitment of the β TrCP-2 component of the Skp1-Cullin1-F-box ubiquitin ligase complex, nonlysine ubiquitylation of tetherin, and ESCRT-mediated trafficking of tetherin for lysosomal degradation.^{79,148,205,225,333} In contrast, tetherin antagonism by HIV-2 Env involves a physical interaction between the extracellular domains of Env and tetherin, and the internalization and sequestration of tetherin within the *trans*-Golgi network, without degradation, by a pathway that depends on a conserved tyrosine-based endocytosis motif in the cytoplasmic tail of gp41.^{122,180} The mechanism of antagonism by Nef remains to be defined, but it appears to involve the downregulation of tetherin from the surface of infected cells.^{149,302}

In accordance with a now familiar theme, resistance to tetherin is species dependent. HIV-1 Vpu counteracts human, chimpanzee, and gorilla tetherin, but is ineffective against the tetherin orthologs of Old World monkeys.^{149,222,289} Conversely, the Vpu proteins of SIVgsn, SIVmon and SIVmus counteract the tetherin proteins expressed by various species of Old World monkeys, but are unable to counteract great ape tetherin.²⁸⁹ Likewise, the Nef proteins of SIVcpz, SIVsmm/mac and SIVagm counteract the tetherin proteins of their respective hosts, and with varying efficiency, the tetherin proteins of other nonhuman primates.^{149,289,382} However, these Nef proteins are universally ineffective against human tetherin.^{149,289,382} The specificity of Vpu reflects amino acid variation in the transmembrane domain of tetherin and corresponding variation in the transmembrane domain of Vpu.^{149,222,289} In contrast, the specificity of Nef for nonhuman primate tetherin is dependent on a five amino acid sequence in the cytoplasmic domain (G/D₁₄DIWK₁₈ in chimpanzee, rhesus macaque, and sooty mangabey tetherin) that is missing from human tetherin.^{149,382}

The absence of sequences in human tetherin that confer susceptibility to Nef has had a profound effect on the evolution of HIV-1 and HIV-2. Since HIV-1 arose from the cross-species transmission of SIVcpz from chimpanzees to humans, and SIVcpz uses Nef to antagonize tetherin, the absence of sequences in human tetherin that confer susceptibility to Nef explains why HIV-1 Vpu acquired this activity in humans. However, this function appears only to have been acquired by the Vpu proteins of the pandemic HIV-1 group M viruses, but not by the nonpandemic HIV-1 group N or O viruses.²⁸⁹ It has therefore been suggested that antagonism of tetherin by Vpu may have contributed to the global spread of HIV-1 group M.²⁸⁹ A similar scenario may explain the role of HIV-2 Env in the antagonism of tetherin. Since HIV-2 arose from the cross-species transmission of SIVsmm from sooty mangabeys to humans, and this virus does not have a *vpu* gene, the inability of Nef to antagonize human tetherin may also account for the selective pressure for HIV-2 Env to acquire this activity.

Compensatory changes in the cytoplasmic tail of gp41 that restore resistance to tetherin were recently identified in a *nef*-deleted strain of SIV that acquired a pathogenic phenotype after serial passage in rhesus macaques. Similar to HIV-2

Env antagonism of human tetherin, these changes result in a physical interaction with rhesus tetherin and facilitate virus release by a mechanism that depends on a conserved tyrosine-based endocytosis motif in the gp41 tail.³⁰² However, unlike HIV-2 Env, these changes afford resistance to rhesus tetherin, but not to human tetherin, by stabilizing a selective physical interaction that depends on residues in the cytoplasmic domain of rhesus tetherin.³⁰² These observations are analogous to the adaptation of HIV-2 Env for antagonism of human tetherin, and imply that antagonism of tetherin is important for virus replication *in vivo* and ultimately for lentiviral pathogenesis.

Receptor Use

HIV-1 uses a sequential two-receptor system that includes both CD4 and a seven-membrane-spanning chemokine receptor for entry into target cells (see Chapter 49). The SIVs that have been examined to date are similar to HIV in their use of both CD4 and chemokine receptors for entry. Like HIV-1, the SIVsm/SIVmac/HIV-2 and SIVagm groups of viruses appear to use CCR5 as the principal second receptor. However, a variety of other chemokine receptors may be used, depending on the virus and the isolate. In addition to CCR5, assorted SIVs have been shown to use CCR2b, CCR3, STRL33 (Bonzo), GPR15 (Bob), and GPR1. The SIVsm/SIVmac/HIV-2 group of viruses in general appears to show less dependence on CD4 for a larger percentage of isolates than does HIV-1.⁸⁴ Use of CXCR4 as second receptor also appears to occur much less frequently with SIVsm/SIVmac than with HIV-1. SIV isolates from red-capped mangabeys (*Cercopithecus torquatus torquatus*) appear to be unusual in their predominant reliance on CCR2b as a second receptor.⁴⁰

Not only does FIV use a two-receptor mechanism to infect cells, it shares with HIV the use of a chemokine receptor (CXCR4) as second receptor for entry.^{267,277,367} FIV infection is modulated by soluble stromal cell-derived factor, the natural ligand for CXCR4¹³⁴ and is inhibited by the CXCR4 antagonist, AMD3100. However, the feline lentivirus uses the T-cell activation marker CD134 as a primary binding receptor rather than CD4.^{64,312} CD134 is a member of the TNF receptor superfamily and has the typical 4-domain structure. The outermost domain is responsible for receptor activity and as few as 5 amino acid changes can make the human homolog a viable receptor for FIV.⁶³ At least certain lion lentiviruses also use CD134 and CXCR4 sequentially for entry,²²⁰ but an unidentified distinct mechanism of entry may be used by the puma lentivirus.^{220,319} The two-receptor mechanism used by the primate lentiviruses and FIV allows the virus to mask critical regions of the envelope protein from the host's immune system in that binding to the primary receptor (CD4 or CD134) causes a conformational change in the envelope to expose sensitive regions involved in high-affinity binding to the chemokine entry receptor. These sensitive regions are thus only exposed transiently to the humoral immune system.

The only other nonprimate lentivirus for which information is available regarding receptor usage is ELAV. The equine virus also uses a member of the TNF receptor superfamily as a receptor, termed ELRI, that is expressed on the primary target for this virus, the macrophage.³⁸⁰ It has been suggested that ELRI may be the only receptor required for infection with the equine virus,^{380,381} with infection occurring "from within"

through vesicles in a pH-dependent manner.²⁸ However, the extent to which EIAV uses one versus a sequential two-receptor mechanism for entry remains to be determined.²⁹

Little information is currently available about the receptors used by other nonprimate lentiviruses. The immediate questions regarding receptor use by lentiviruses are obvious ones, but the answers will be instrumental in our understanding of the evolution and logic of receptor use. Do all lentiviruses use a two-receptor system for entry into target cells? Is the second receptor always a seven-membrane-spanning chemokine receptor? Is use of a chemokine receptor a theme common to all lentiviruses? What is the nature of the other primary receptors that are used? Did evolutionary changes result in a switch from a one-receptor system (chemokine receptor) to a two-receptor system (X + chemokine receptor), or a switch from one two-receptor system (X + chemokine receptor) to another (CD4 + chemokine receptor)?

Germline Integration

Many retroviruses not only infect their hosts exogenously but also are inherited in Mendelian fashion, either as highly defective genomes, single LTRs, or in the case of the murine and feline gammaretroviruses as inducible infectious agents. However, endogenous genomes of lentiviruses have not been found in the germlines of most species that have been examined, including humans and nonhuman primates; thus, such germline integration must be a much rarer event for the lentiviruses. There are, however, now two examples of germline transmission of nonreplicating lentiviral elements. The first was noted in the European rabbit (*Oryctolagus cuniculus*), with unmistakable lentivirus characteristics, yet totally unique from any known “modern” lentivirus in overall structure.¹⁵⁹ The second was identified in the genome of the grey mouse lemur (*Microcebus murinus*) of Madagascar.¹⁰⁷ Both of these primordial lentiviruses offer a plethora of information relevant to better understanding of how long lentiviruses have been around as infectious agents, the nature of lentiviral genome plasticity, and the selective forces that may have shaped lentiviral evolution in the past.

Analysis of the rabbit endogenous lentivirus termed RELIK (rabbit endogenous lentivirus type K) revealed a tRNA_{Lys} primer binding site, a hallmark of lentiviruses and, in addition to *gag*, *pol*, and *env*, evidence for both *tat* and *rev* genes. The genomic organization for RELIK is the simplest of known lentivirus structures, with greatest similarity to EIAV based on the presence of a gene encoding dUTPase in *pol*, but lack of a *vif* gene found in other nonprimate lentiviruses. The genomic data, presence of pairs of insertions that had arisen through segmental duplication of the host genome, and the number of single LTRs present in the rabbit genome, suggests an approximate age for RELIK of 5.7 to 7 million years. This is in comparison to a calculated age for more modern transmissible lentiviruses of felines and primates of 1 to 2 million years.¹⁵⁹ A later study of an ortholog of RELIK in the European hare (*Lepus europaeus*)¹⁶¹ allowed comparisons of divergence rates in the context of two lagomorph species, yielding an approximate age for RELIK of 12 million years! Thus, lentiviruses, formerly thought to be of relatively recent origin, may be much older.

The lemur endogenous element likewise showed characteristics that identified it as a lentivirus, with evidence that it represents the primordial ancestor to modern SIVs.¹⁰⁷ The virus, termed pSIVgml (grey mouse lemur prosimian immunodeficiency virus), has features more resembling the complex lentiviruses, including *vif*, *tat*, and *rev* genes but lacks evidence for *vpr* and *vpu* genes. A putative 3′ gene is present in the relative position of *nef*, but it bears no identifiable sequence relationship. The overall genomic structure puts pSIVgml closer to FIV than to the other nonprimate lentiviruses. Of particular relevance to lentiviral evolution, pSIVgml has a gene for dUTPase between the RNase H and integrase coding regions of *pol*. This characteristic is lacking from the modern primate lentiviruses but present in the nonprimate lentiviruses. The presence of dUTPase establishes with good authority that modern primate lentiviruses lost coding capacity for this gene product as opposed to never having acquired it. As with the rabbit lentivirus, the presence of identical viral elements in segmental duplications, frequency of single LTRs, and lack of heterozygous insertion sites arising from homologous recombination is consistent with great antiquity for the virus in the lemur genome. By comparing to estimated rates of mouse and human neutral evolution, the authors calculate that pSIVgml is 1.9 to 3.8 million years old. Given the likely introduction to Madagascar via the last mammalian terrestrial incursion, the evidence suggests that lentiviruses have circulated in the population at least 14 million years. These forays into paleovirology will continue to be of value in better understanding the origins and evolutionary history of the lentiviruses.

ciency virus), has features more resembling the complex lentiviruses, including *vif*, *tat*, and *rev* genes but lacks evidence for *vpr* and *vpu* genes. A putative 3′ gene is present in the relative position of *nef*, but it bears no identifiable sequence relationship. The overall genomic structure puts pSIVgml closer to FIV than to the other nonprimate lentiviruses. Of particular relevance to lentiviral evolution, pSIVgml has a gene for dUTPase between the RNase H and integrase coding regions of *pol*. This characteristic is lacking from the modern primate lentiviruses but present in the nonprimate lentiviruses. The presence of dUTPase establishes with good authority that modern primate lentiviruses lost coding capacity for this gene product as opposed to never having acquired it. PATHOGENESIS AND PATHOLOGY

Portals of Entry

The primary modes of natural transmission of the nonhuman lentiviruses vary considerably with the virus. EIAV may be the most interesting because it is the only lentivirus for which there is good evidence for vector-borne transmission. During disease episodes, levels of infectious virus in the plasma of horses can exceed 10⁴/mL. The horsefly appears to be more efficient than mosquitoes, fleas, or other insects for being able to transmit EIAV. Transmission has been documented by following a single horsefly that had taken a blood meal on an infected pony during an acute clinical period.¹⁴⁶ Transmission via blood can also be mediated by inappropriate veterinary practices with needles or scalpels.

Work on natural modes of infection has demonstrated the capability of both vertical and horizontal transmission for FIV, MVV/CAEV, and EIAV.³³ Vertical transmission can occur *in utero*, during parturition, and postnatally via milk. This vertical transmission by these viruses parallels that observed with HIV in humans. Contact transmission also is common, particularly for MVV/CAEV and EIAV, when animals are herded closely together in barns or stables. These viruses can be found in semen, lung excretions, and saliva. For cats, bite wounds are believed to be the most important route of transmission in adult animals.³⁷³ Transmission via grooming/licking has also been observed,⁶⁶ and consistent experimental infection of cats can be achieved via oronasal administration. FIV infection is much more prevalent in free-roaming males than in females, consistent with increased fighting and biting among male cats. Cats allowed to roam free in areas with high cat density are at greatest risk of becoming infected.

Information about natural modes of SIV transmission has been harder to come by. One study of wild grivet monkeys in Awash National Park in Ethiopia analyzed SIVagm serologic

status with age, sex, and risk.²⁶² Infection was nearly universal in females of reproductive age and nearly absent in younger females. In males, infection was observed in only those that were fully adult. The findings support a predominantly sexual mode of SIV transmission among grivets. Male-to-male transmission by aggressive contacts may also be a prominent mode by which SIV can be spread.²³⁹ Maternal–infant transmission of SIV has been documented in captive animals.¹⁷¹

Experimental infection of laboratory animals has been commonly achieved by direct needle inoculation. However, mucosal exposure is now being used more frequently, particularly for vaccine studies, as a model for the most common routes of HIV transmission.

Cell and Tissue Tropism

Despite the varied modes of transmission, all lentiviruses are disseminated to an assortment of tissue sites by the blood. A virus can be disseminated as a free virus or, more likely, by infected blood monocytes or lymphocytes. Differences in the cell tropism of primate versus nonprimate lentiviruses relate largely to receptor use discussed earlier. Infection by the primate lentiviruses SIV and HIV is seen in CD4⁺ lymphocytes and macrophages, with CD4⁺ lymphocytes vastly predominating in terms of numbers of infected cells. For the nonprimate lentiviruses, infection of macrophages typically predominates, but infection can be seen in a greater diversity of cell types. Replication in tissue macrophages is a unifying feature of all lentiviruses.

The principal anatomic sites for localization of MVV and CAEV have varied with the study and strain of virus used. Because many studies of virus localization have used experimental infection, the origin of the infecting strain and type of cell in which it was grown must be taken into account when interpreting the results of these studies. Various reports have localized MVV principally to lungs, mammary glands, joints, lymph nodes, the spleen, and the brain. The principal target cell in which MVV and CAEV sequences can be found *in vivo* is consistently the tissue macrophage. However, in keeping with the broad range of cell types that can support replication in culture, evidence has been presented for MVV/CAEV replication in other cell types in a less prominent fashion, including epithelial and fibroblast cells in choroid plexus, intestine, and kidneys. An important observation first made with MVV is that although virus may reside in the relatively undifferentiated monocytes in peripheral blood, MVV expression is greatest in the differentiated tissue macrophages.^{104,259} This led to the concept of the “Trojan horse” for MVV and other lentiviral infections, whereby undifferentiated monocytes in the peripheral blood may carry the viral genome without sustaining viral replication until transported to tissues and differentiated into their mature form, the tissue macrophage.

Anemia caused by EIAV is hemolytic and results from the formation of antigen–antibody complexes that can associate with the surface of erythrocytes. The kidney also is affected by this complex formation. A variety of studies, both old and new, have shown the tissue macrophage to be the major cell type producing EIAV.^{221,248,301} Virus production has been noted in the spleen, liver, kidney, lymph nodes, lung, heart, brain, stomach, bone marrow, thymus, adrenals, and intestine. Although EIAV can be adapted to replicate on fibroblasts, the virus that comes out of horses during viremic episodes is derived principally from macrophages.

FIV appears to be unusual among the nonprimate lentiviruses in that the virus has been more consistently found in a broader range of cell types, particularly lymphocytes, in addition to macrophages. Analyses of tissue and cellular localization of FIV have principally used experimentally infected cats and FIV grown in lectin-stimulated peripheral blood mononuclear cell (PBMC) cultures in the presence of interleukin-2. However, studies with naturally infected cats have yielded similar findings. FIV has been found in a variety of cell types including CD4⁺ T lymphocytes, B cells, CD8⁺ T cells, macrophages, bone marrow–derived cells and cells of the central nervous system (CNS). Macrophages, microglia, and astrocytes, but not neurons, in the brains of cats have been found to be targets of FIV infection.⁸⁰ The propensity of FIV to replicate in and deplete CD4⁺ T lymphocytes now makes sense in the light of use of the activated T-cell marker CD134 (OX40) as primary binding receptor and CXCR4 as second receptor for entry into cells.^{63,64,312}

The major sites of pathogenic SIV replication early after infection have been localized to gastrointestinal (GI) tract, thymus, spleen, and other lymphoid tissue.^{176,351} SIV was localized at these early time points within periarteriolar lymphoid sheaths in spleen, paracortex of lymph nodes, and medulla of the thymus. Many early studies overlooked the fact that the GI tract contains most of the lymphoid tissue in the body. Further, the T lymphocytes are activated and express CCR5 in great abundance. SIV infection of rhesus monkeys results in profound and selective depletion of CD4⁺ T cells in the intestine within days of infection, before any such changes are evident in peripheral lymphoid tissues. The loss of CD4⁺ T cells in the intestine coincides with productive infection of large numbers of mononuclear cells at this site. Thus, the GI tract appears to be a major target for SIV replication and the major site of CD4⁺ T-cell loss early in SIV infection.^{351,352} It is now clear that SIV replicates principally or exclusively in CD4⁺ CCR5⁺ cells, which represents a subset of memory T cells.¹⁸⁹ One exception to the predominant use of CCR5 is the X4-using SIV strain SIVmac155T3.²⁶³ CD4⁺ CCR5⁺ lymphocytes predominate in the gut and other mucosal sites and are present at much lower frequency in peripheral lymphoid organs. Subsequent to these pioneering studies with SIV in monkeys, the gut-associated lymphoid tissues were also shown to be a major site of HIV-1 replication during acute infection in humans.^{26,224} The predominate replication in the human gut is again associated with the marked preference for CD4⁺ CCR5⁺ memory cells.²¹⁷ Within the thymus, marked depletion of thymic progenitors has been noted by 21 days after rhesus monkey infection with pathogenic SIV; this depletion is followed temporally by increased levels of cell proliferation in the thymus and a marked rebound in thymocyte progenitors.³⁷² The distribution of virus within lymphoid organs varies with the inoculum. SIV also can be found in the CNS early after infection. The infected cells in the brain, whether early after infection or late in SIV-induced encephalitis, are primarily cells of monocyte/macrophage lineage.²⁸⁸ These may include perivascular monocyte/macrophages that have migrated from the blood or the resident microglial cells.

Immune Responses and Persistence

Monkeys infected with SIV and animals infected with other lentiviruses typically make strong antibody and cytotoxic T lymphocyte (CTL) responses to the virus. These immune responses persist at high levels for the lifetime of the infected host, whether

FIGURE 51.5. Attenuation by auxiliary gene deletion lowers viral load and reduces the strength of the antiviral antibody response. SIVmac239Δ4 has inactivating deletions in *vpr*, *vpx*, and two in *nef*.

infection is by natural or experimental means. Approximately 20% to 30% of macaque monkeys infected with some AIDS-causing strains of SIV develop a more rapid disease course, make few or no antibodies to the virus, and die with AIDS in 3 to 7 months. The deficiency in anti-SIV antibodies in such animals does not appear to be a matter of antigen excess because B cells from these rapidly progressing monkeys make few or no anti-SIV antibodies.⁸³ The strength of anti-SIV antibody responses also varies with the virulence of the infecting strain (Fig. 51.5). Deletion mutants of SIV that are progressively more attenuated on the basis of viral load measurements elicit progressively weaker anti-SIV antibody responses.⁶⁹ CTL responses have been shown to be major histocompatibility complex (MHC)–restricted for both SIV and animal lentiviruses. A considerable amount of new information has now emerged about MHC alleles in rhesus monkeys and the peptides that they present, which is facilitating detailed work on CTL responses.

The importance of CD8⁺ lymphocytes in limiting the extent of replication of SIV or SIV/HIV recombinant (SHIV) has been definitively demonstrated by using the approach of CD8-cell depletion.^{216,296} Extensive depletion of CD8⁺ cells was achieved by intravenous administration of large doses of specific anti-CD8 monoclonal antibodies. Depletion was not permanent because CD8⁺ lymphocytes returned in the absence of continuous monoclonal antibody. When CD8⁺ cells were depleted during primary infection, virus replication proceeded unabated after peak loads 10 to 14 days after infection; this contrasts with nondepleted animals, in which immune responses typically result in reductions in viral loads beyond 14 days.^{216,296} Elimination of CD8⁺ lymphocytes from monkeys during chronic SIV infection resulted in a rapid and marked increase in viremia that was again suppressed coincident with the reappearance of SIV-specific CD8⁺ T cells.²⁹⁶ Depletion of CD8⁺ T cells in SHIV-infected animals has facilitated the appearance of more highly pathogenic variants.¹⁴¹

In SIV-induced disease in macaque monkeys with wild-type strains of SIV, viral-specific, proliferative responses of CD4 cells are typically weak or absent. However, infection by attenuated SIV mutants deleted in *nef* results in strong, SIV-specific, CD4 helper cell proliferative responses.^{101,102} This situation appears analogous to HIV infection of humans in which

HIV-specific CD4 proliferative responses are usually weak or absent in typical progressors but are often strong in unusual nonprogressors that are controlling their infection.^{282,283} The picture that emerges with these primate CD4 receptor–using viruses is one of a battle during the early stages of infection. CD4 helper cells try to respond to sites of infection, but these activated CD4 cells at the sites of infection are the ideal targets for replicating virus. In pathogenic infections, the virus wins this early battle and eventually wins the remainder of the war. SIV-specific CD4⁺ helper cell responses have been observed in nonpathogenic infection of natural hosts, but their effectiveness is uncertain.^{82,360}

Lentiviral persistence is achieved via chronic active viral replication. The clearest demonstrations of this are with HIV in humans and SIV in macaque monkeys; during months or years of chronic infection, millions of viral particles and millions of infected cells are produced and turned over every day.^{131,362} This does not mean, however, that no cells are infected in a quiescent or latent fashion; some certainly are. The degree of chronic active replication also varies with the strain of virus and the host. The long-term persistence of antibody and CTL responses at high levels is consistent with the prolonged antigen expression of chronic active replication. Even nonpathogenic derivatives of SIV continue to replicate at low levels over prolonged periods, as evidenced by the evolution of sequence changes, persistence of antibody, and other criteria.

EIAV is unusual among the lentiviruses for the episodic nature of the persistent viral replication. Infection of horses with EIAV is associated with recurring episodes of fever, anemia, and thrombocytopenia. These episodic occurrences of clinical disease coincide with bursts of new virus replication, which may be weeks or months apart. Episodes of new virus replication yield EIAV variants that are not neutralized by the horse's own serum; however, the same serum is capable of neutralizing the EIAV variants from earlier episodes.²²⁸

The dilemma of lentiviruses is their ability to replicate persistently in the face of apparently strong immune responses. The levels of anti-HIV antibody and CTLs have been precisely measured and are enormously high. The strategies used by lentiviruses to allow persistent viral replication in the face of these apparently strong immune responses have been reviewed.^{72,87,156} These are summarized in Figure 51.6 and in points 1 through 5 below.

1. **Differentiation- or activation-dependent expression:** Like all retroviruses, the lentiviruses integrate a proviral DNA copy of their genetic information into the host cell DNA. This proviral DNA may lie dormant for prolonged periods and can be reactivated at a later date when conditions may be more suitable. Triggering events for activation of lentivirus expression can include cellular activation of lymphocytes or macrophages by natural stimuli (antigen, cytokines) and differentiation of monocytes into tissue macrophages, as originally promulgated in the Trojan horse concept.
2. **Emergence of antigenic variants:** As RNA viruses, the lentiviruses have an error-prone reverse transcriptase (RT) for replicating their genetic information. The emergence of mutant forms of virus (within a single infected individual) that are antigenic variants that escape ongoing neutralizing antibody responses was first described with EIAV, MVV, and CAEV. Subsequent work has provided exquisite detail

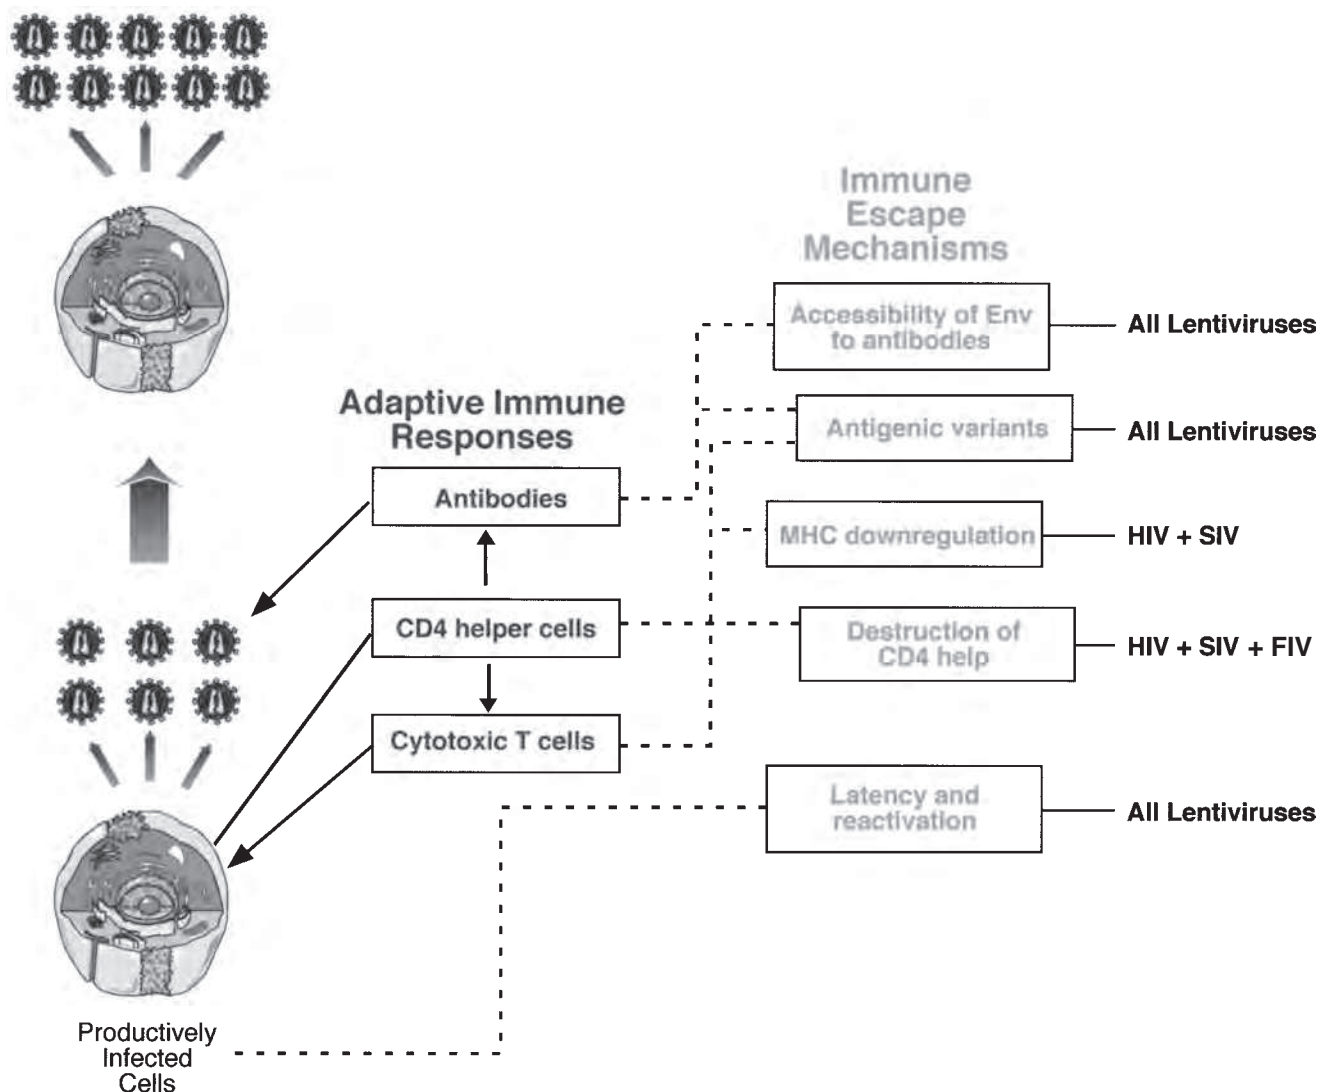

FIGURE 51.6. Human immunodeficiency virus (HIV), simian immunodeficiency virus (SIV), and other lentiviruses use a variety of strategies to avoid both humoral and cellular responses.

on the emergence of SIV and HIV variants that escape both neutralizing antibody and CTL responses.^{24,31,32,88,278,361}

3. *Shielded nature of external surface glycoprotein:* The surface proteins of all lentiviruses are heavily glycosylated; in fact, the external surface glycoproteins (GPs) of lentiviruses are among the most heavily glycosylated mammalian cell proteins known. The carbohydrate groups help to serve as a barrier that limits the neutralizing antibody response to virus. Strains of SIV lacking specific carbohydrate attachment sites are more effective targets for antibody-mediated neutralization and some are able to elicit considerably higher titers of neutralizing antibodies.^{35,43,275} As mentioned previously, the two-receptor mechanism for attachment and entry also allows a certain degree of shielding of internal sites that are conserved in sequence.

The only lentiviral surface GPs for which three-dimensional data are available are HIV-1¹⁷⁵ and SIV.³⁹ Although the structures lack variable loop sequences and carbohydrate to varying degrees, a compilation of antibody mapping

and structural and functional data have revealed interesting features that reflect on the replication strategy. The CD4-binding site is contained within a difficult-to-access pocket, and the variable loops and carbohydrate appear to act largely as a shield to protect regions of the protein that would otherwise make the virus sensitive to antibody attack. The envelope proteins of HIV and SIV are packed tightly in a trimer to form the spike on the surface of virions. While monomeric gp120 is readily reactive with glycosidases and antibodies, gp120 as it exists on the surface of virions is difficult for glycosidases and antibodies to access.^{223,254} Although infected people develop high-titer antibody responses reactive with monomeric HIV-1 envelope protein, these antibodies apparently react poorly or not at all to envelope protein as it exists on the surface of virions. These antibodies in general have poor neutralizing activity.

4. *Destruction of CD4 help:* This immune evasion strategy appears to be applicable only to the primate lentiviruses, which use CD4 as a primary receptor, and FIV, which uses

CD134 as a receptor. The early destruction of virus-specific CD4 helper cell activity leaves the host without appropriate help for its B-cell and CD8-cell responses.⁷⁸

5. **MHC downregulation:** The primate lentiviruses encode an early gene product, Nef, that downregulates MHC class I molecules from the surface of cells, making them less-sensitive targets for CTL attack.^{48,300,329}

Other RNA viruses with error-prone polymerases, such as poliovirus, seem nowhere near as difficult to neutralize and nowhere near as malleable as HIV. The basis for these differences may lie in the inherent strategies used by persisting versus nonpersisting viruses. The survival of any virus depends on its ability to spread through the population. For a nonpersisting virus such as poliovirus, transmission is typically limited to the several weeks after the time of primary infection. Resistance to antibodies, once they appear, may not be so important to such a virus. Instead, it is important to replicate maximally for the brief period to maximize the likelihood for transmission. HIV, SIV, and other lentiviruses, in contrast, help to ensure their transmission by greatly lengthening the period during which transmission can occur. Thus, these viruses may sacrifice inherent replicative capacity in the short term to allow persistent viral replication over the long term.

Virulence

Not all lentiviral infections are uniformly pathogenic. The various forms of SIV are in general not associated with disease in their natural hosts. Lifelong subclinical infections also have been documented for EIAV and MVV. Breeds of horses and sheep vary in their general susceptibility to EIAV and MVV, and these may even vary in the degree of susceptibility to specific disease manifestations. For example, the classic CNS form of visna infection originally observed in Iceland is only rarely seen elsewhere. Some strains of SIV are much less pathogenic than others in susceptible macaque monkeys, and some derivatives that have been specifically attenuated by deletion mutations appear to be nonpathogenic. There are a few examples of AIDS-like disease in African monkey species naturally infected with SIV.^{196,219,252}

The diseases associated with lentiviral infections are typically chronic and manifest over a prolonged period. However, there are some prominent exceptions to the classic, prolonged course of lentiviral disease. A particular strain of SIV called SIVsmPbJ14 is acutely lethal in rhesus monkeys. Monkeys infected with SIVsmPbJ14 typically die within 14 days with very high viral loads, severe GI disease, cytokine dysregulation, lymphoproliferative disease, and organ system failure.^{74,93,95,245} The unusual properties of this strain have been attributed in large part to the unusual positioning of a tyrosine at residue 17 of the nef protein.⁸¹ The occurrence of tyrosine at this position of nef creates an immunoreceptor tyrosine-based activation motif (ITAM) of the type YXXLX₇YXXL that imparts on the virus the unusual ability to cause lymphocyte activation and to replicate to high titers in lymphocytes of PBMC cultures without any prior stimulation.⁸¹ The BIV variant that is the cause of Jembrana disease in Bali cattle also is acutely pathogenic. About 17% of Bali cattle infected either naturally or experimentally with JDV die with an acute disease within the first few weeks.^{75,76,366} During acute disease, infectious titers of virus reach 10⁸/mL of plasma. JDV has remarkable similarities to the

disease induced by the tyrosine-*nef* variant of SIV, SIVsmPbJ. In JDV, there is marked enlargement of lymph nodes and spleen, which feature proliferating lymphoblastoid cells. Proliferating lymphoid infiltrates are also found in many other tissues. The disease in horses induced by EIAV also is often considered more acute than that occurring with other lentiviruses. The first episode of EIA disease usually occurs 2 to 6 weeks after the initial infection. Subsequent disease cycles are irregular, appearing weeks to months apart, and usually last 3 to 5 days. The frequency and severity of disease episodes usually decline with time. Episodes of clinical disease usually end within the first year after an average of six to eight episodes.

Everything that we know about the pathogenesis of AIDS in macaques with SIV and in humans with HIV-1 points to the importance of viral loads. High viral loads bode poorly; low viral loads predict an improved prognosis. Because sooty mangabeys and African green monkeys do not get sick from the SIVs with which they are naturally infected, most scientists assumed that the viral loads in these species would be low. Quite unexpectedly, by and large they are not.^{30,108,276} Naturally infected sooty mangabeys and African green monkeys live a normal life with plasma viral RNA loads of 10⁵ to 10⁶, viral loads that are lethal in SIVmac-infected macaques and HIV-1-infected humans. The SIVsm and SIVagm viruses infecting these species are fully capable of inducing AIDS, since they do so when passaged in macaques. A distinguishing feature of natural hosts who are able to resist disease despite high viral loads is the absence of chronic lymphoid activation. A strong case has been made that the chronic lymphoid activation that is the hallmark of SIV- and HIV-induced AIDS results at least in part from “microbial translocation,” that is, the chronic release of bacterial antigens from the confines of the gut into the circulation.²⁵

Clinical and Pathologic Features

Good reviews are available on the clinical and pathologic features of nonhuman lentiviral infections.^{33,157} Some of the most prominent features are highlighted here.

Equine Infectious Anemia Virus

Equines are the only species susceptible to natural or experimental infection with EIAV. Clinical disease is usually divided into acute, subacute, and chronic phases. Acute disease typically results in fever as high as 108°F 1 to 4 weeks after infection. Anemia is not a prominent feature at the outset. Excessive thirst, loss of appetite, weakness, depression, and hemorrhage are seen in the acute phase. The acute form may result in death. The subacute form is characterized by relapsing fever and recurrence of other signs. Recurrence of episodes may be brought on by hard work or malnutrition. In its chronic form, animals may remain thin despite adequate availability of food, and red cell counts are typically well below normal. Clinical signs in late disease and pathology findings appear to result principally from hemolytic anemia. Erythrocytes of infected horses are coated with antibodies and complement factor 3, and destruction of red cells is immunologically mediated. Osmotic fragility, shortened half-life, and phagocytosis contribute to the destruction. Bone marrow may also be depressed, but this seems less important than immune-mediated destruction. Hemorrhage, jaundice, and edema are most commonly found at necropsy. The nature and severity of the lesions will vary with course of disease and duration of the illness.

Maedi/Visna Virus and Caprine Arthritis Encephalitis Virus

Although maedi (pneumonia) and visna (wasting, depression, paralysis) were once thought to be separate diseases, it is now clear that they are both caused by the same virus. Both systems can be affected in the same animal. Maedi disease in the Netherlands has been called *zwoegerziekte*. Polyarthritis and mastitis also are seen as a result of viral infection. Disease is usually seen only in adult sheep because of the lengthy incubation period, typically 3 to 8 years. The lungs of affected sheep may

be two to five times the normal size, and they exhibit a rubbery loss of elasticity. These abnormalities result from a gross thickening of the alveolar walls from infiltration and proliferation of reticuloendothelial or mesenchymal cells that invade the septa everywhere (Figs. 51.7A and 51.7B). Lymph nodules occur along the bronchi and bronchioles. There is progressive weight loss. Dyspnea is initially apparent only after exercise, but it progresses. Severely dyspneic sheep spend much time lying down. Lesions in the brain consist of demyelination and lymphocytic infiltration (Figs. 51.7C and 51.7D). Trembling

FIGURE 51.7. Pathology of maedi/visna virus (MVV) in sheep. A,B: Pneumonia. **C,D:** Encephalitis. (From Johnson W, Desrosiers RC. Viral persistence: HIV's strategies of immune system evasion. *Annu Rev Med* 2002;53:499–518.)

of facial muscles and lips may occur. The onset of clinical signs of visna usually begins with weakness of the hind legs, which eventually leads to paraplegia. Diseases caused by CAEV in goats are similar to those of MVV in sheep except that arthritis is usually most prominent and the pneumonia is usually of lesser severity. Joints are swollen and painful, exacerbated by cold weather. The basic lesion is a proliferative synovitis of joints, tendon sheaths, and bursae.

Feline Immunodeficiency Virus

Primary infection by FIV may lead to low-grade fever, generalized lymphadenopathy, and sometimes diarrhea. During the ensuing months and years, progressing disease is associated with lymphopenia, recurrent fever, lymphadenopathy, anemia, diarrhea, and weight loss of protracted duration. CD4 counts and other cell subsets may be depressed. The final stages of disease are associated with chronic secondary infections, particularly gingivitis, dermatitis, and infections of the upper respiratory tract. Opportunistic infections that have been observed include calicivirus, herpesviruses, toxoplasma, and cryptococcus. Neurologic abnormalities also have been noted, including dementia, twitching tremors, and convulsions. Pathologic lesions primarily reflect those of opportunistic infection.

Simian Immunodeficiency Virus

SIV infection of rhesus monkeys is generally considered the closest model of AIDS in humans. SIV infection of the natural host (e.g., SIVagm in green monkeys or SIVsmm in sooty mangabey monkeys) is in general not associated with any disease, although there may be occasional exceptions.^{196,219,252} When SIVsmm was inadvertently introduced into captive macaque monkey species (Asian Old World primates), AIDS-like disease and lymphomas did ensue.^{8,61,208} AIDS-like disease is generally induced experimentally in macaque monkeys with SIVmac, SIVsmm, or less frequently SIVagm. As with other lentiviruses, SIV establishes a chronic active infection with a prodromal period of months to years before clinical signs appear. Immunodeficiency is usually, but not always, associated with marked declines in CD4⁺ lymphocyte concentrations. Macrophages also are infected. Pathologically, generalized lymphadenopathy is characterized by hyperplasia and is followed by lymphoid depletion in terminal stages (Figs. 51.8A and 51.8B). The GI tract, where activated T lymphocytes predominate, appears to be the major site of early viral replication and early loss of CD4⁺ T cells (Fig. 51.8C).³⁵¹ However, CXCR4-using viruses may cause a profound loss of T cells in the periphery that is not paralleled in the intestine.²⁶³ Marked depletion of progenitor cells occurs in the thymus by 21 days; although a rebound occurs subsequently, thymic dysinvolution is typically seen at terminal stages (Figs. 51.8D and 51.8E).³⁷² Nodular lymphocytic infiltrates in a variety of tissues (Fig. 51.8C), interstitial pneumonia with syncytial cells (“giant cell pneumonia”) (Figs. 51.8H and 51.8I), and granulomatous encephalitis (Fig. 51.8F and 51.8G) are variably present. Opportunistic infections are usually present, which can influence the specific nature of the clinical signs. Common opportunistic infections include *Pneumocystis carinii* pneumonia, generalized cytomegalovirus, cryptosporidiosis, and *Mycobacterium avium*.

Many research groups have now constructed recombinant forms of SIVmac with HIV-1 *env*, *tat*, *rev*, and in some cases *vpu* genes called “SHIV” (for SIV-HIV hybrid) and selected for

pathogenic forms by passage in macaque monkeys.^{118,141,142,152,274} A uniform feature of these early, independently passaged SHIV constructions is that they rapidly and irreversibly deplete CD4⁺ T lymphocytes from the periphery.¹⁴⁰ Although most of the HIV-1 envelopes from which these SHIVs were derived are dual-tropic in that they can use either CXCR4 or CCR5 for entry in cultured human cells, in rhesus monkeys they appear to target CXCR4-expressing cells almost exclusively.²⁴² R5-using SHIVs are under development,¹¹⁸ but none have been found yet to consistently induce a chronic disease course similar to SIVmac251, SIVmac239, or SIVsmE660.

Contributions of Individual Genes and Genetic Elements

Because lentiviruses, like other retroviruses, replicate through a proviral DNA intermediate, cloned proviral DNA representing the full-length lentiviral genome can be infectious. Infectious lentiviral DNAs have been used to study the contributions to replication of open reading frames not found in other retroviruses. The unusual, persistent nature of lentiviral replication has raised speculation as to the role of auxiliary genes in the persistent replication and chronic disease of the lentiviruses. Infectious, cloned, lentiviral DNAs also have been used to gauge the relative importance and functional role of auxiliary genes in the context of experimental animal infection. The first cloned lentiviral DNA shown to be not only infectious but also pathogenic was one for SIV.¹⁶³ Infectious clones that are also pathogenic are now available for EIAV, CAEV, FIV, and other SIV isolates.^{50,66,125,255}

Deoxyuridine Triphosphatase

A dUTPase reading frame is located within the *pol* gene of the nonprimate lentiviruses and in the transition region between *gag* and *pol* in the type D beta retroviruses. dUTPase catalyzes the conversion of dUTP to dUMP and inorganic pyrophosphate. dUMP is an important precursor for dTTP, used for incorporation into DNA. dUTPase activity in the cell is believed to minimize misincorporation of dUTP into DNA, which can be mutagenic. The effects of eliminating the dUTPase gene (*DU*) have been studied in EIAV, FIV, CAEV, and visna. In all cases, *DU*⁻ virus was still replication competent in cultured cells. Loss of *DU* in EIAV and FIV had little or no effect on virus replication in permissive fibroblast cell lines that continuously divide. However, loss of *DU* in these viruses had dramatic effects on virus replication in macrophages.^{332,358} Macrophages are not dividing cells and in general have low deoxynucleotide pool sizes. *DU*⁻ EIAV exhibited five- to 10-fold lower viral loads in plasma at peak compared with the parental virus, and both EIAV and CAEV missing *DU* were attenuated for pathogenicity.^{192,358} *DU*⁻ FIV and CAEV were found to accumulate increased levels of mutations, particularly G-to-A transition mutations.^{185,340} Visna viruses lacking *DU* also showed decreased viral loads in experimentally infected sheep but still produced neuropathogenic effects upon direct intracerebral inoculation.²⁶¹

Tat and Rev

The *tat* proteins of lentiviruses can be clearly divided into two groups with respect to whether or not their transactivating activities are dependent on binding to an RNA sequence element.^{23,65,229} HIV, SIV, EIAV, and BIV all have long terminal repeats (LTRs)

FIGURE 51.8. Acquired immunodeficiency syndrome (AIDS) in monkeys: histopathologic lesions and simian immunodeficiency virus (SIV) localization. **A–C:** *In situ* hybridization for SIV RNA in lymph nodes (**A,B**) and intestine (**C**). In **A**, numerous individual positive cells can be seen in the paracortex of the lymph node of an animal 8 weeks after infection. In addition, diffuse staining of the germinal center (**GC**) of a lymphoid follicle consistent with trapping of virus on follicular dendritic cells can be seen. Note that the lymphoid architecture is relatively intact at this early time point, in contrast to a lymph node from an animal with terminal AIDS in **B**. Although the lymph node in **B** shows severe lymphoid depletion with no evidence of lymphoid follicles, numerous SIV-infected cells can be seen. In **C**, numerous infected cells in the intestine can be seen in a submucosal lymphoid nodule with a rare positive cell (*arrow*) in the overlying lamina propria of this animal 2 months after infection. **D,E:** Thymic atrophy. Infection with SIV is associated with profound dysinvolution of the thymus (**D**), as opposed to a normal thymus (**E**) with discrete cortex and medulla. **F,G:** SIV encephalitis. Infection with SIV results in inflammation of the brain in 25% to 50% of the animals that are infected. The brain lesions are characterized by aggregates of mononuclear cells and multinucleated giant cells (**F**). Cells in the lesions contain abundant SIV nucleic acid by *in situ* hybridization (**G**). **H,I:** Giant cell pneumonia. Multinucleated giant cells in this pneumonia (**H**) as well as numerous mononuclear cells contain abundant SIV nucleic acid by *in situ* hybridization (**I**). (Courtesy of Dr. Andrew Lackner.)

with low basal activity that is strongly induced by their respective Tat proteins in a cyclin T1- and RNA sequence-dependent fashion. The LTRs of visna and FIV are strongly active in the absence of any viral proteins. Recent reports now indicate that the gene called *tat* in visna virus and OrfA in FIV may actually be more Vpr-like in their activities.^{37,103,354} FIV OrfA has now been shown to facilitate decreased CD134 receptor expression on the cell surface by sequestration in the Golgi complex,¹³³ analogous to similar activities for Vpu and Nef of primate lentiviruses. It is debatable whether there is any viral-induced transcriptional transactivation with FIV and MVV; if it exists, it is weak. BIV Tat is unusual in that it is able to bind to the RNA sequence element independent of cyclin T1, but transactivation is nonetheless dependent on the participation of cyclin T1.²³

Tat and *rev* are essential for the replication of SIV and HIV. The *rev* genes of MVV and CAEV have also been found to be essential for replication.^{297,335} *Tat* appears to be essential for replication of BIV and EIAV as well. But it is only a weak transactivator in CAEV, and it was found to be dispensable for efficient viral replication both in culture and in goats.¹¹⁷ Although *rev* is essential for SIV replication, von Gegerfelt et al.³⁵⁶ have described a strain of SIV lacking both *rev* and the *rev* response element (RRE) that becomes replication competent with the addition of a constitutive transport element (CTE). The loss of *rev* and RRE and the addition of the CTE appeared to have a significant attenuating effect.³⁵⁶ Because antibodies persisted for more than a year without decline, the *rev*⁻ RRE⁻CTE⁺ SIV appeared to have established a persistent infection but at low levels.

S2

An EIAV derivative lacking S2 replicated normally in fetal equine kidney cells, monocyte-derived macrophages, and differentiated macrophages.¹⁸⁷ The S2 deletion mutant displayed slightly decreased viral loads and thrombocytopenia-inducing potential when compared with the parental cloned EIAV.¹⁸⁶ Infected horses consistently make antibodies to S2, confirming that S2 is a bona fide virus-encoded product. Recent studies have shown that S2 causes a marked upregulation of pro-inflammatory cytokine and chemokine expression in infected macrophages, which may contribute to the rapid and early acute clinical disease unique to EIAV infection.⁵⁶

Vif

With the exception of EIAV, all lentiviruses have a *vif* gene (Tables 51.4 and 51.5). Vif is required to overcome a producer-cell block to virus infectivity imposed by members of the APOBEC family of cytidine deaminases.^{21,193,307,365,384} Accordingly, Vif is critical for virus replication *in vivo* and in cells expressing APOBEC3G and APOBEC3F.^{69,303} In the absence of Vif, APOBEC3G and 3F become incorporated into virus particles and catalyze the cytidine deamination of minus-strand DNA during the next round of reverse transcription.^{119,182,206,383} Extensive cytidine deamination of the minus strand leads to the accumulation of G-to-A transitions in the plus strand and inactivation of the viral genome as a result of catastrophic hypermutation (see previous section on Restriction). Vif counteracts this restriction by recruiting the cullin-5-elongin B/C-Rbx ubiquitin ligase complex, which mediates the polyubiquitylation and proteasomal degradation of APOBEC3G and 3F.^{49,211,306,378} By promoting the depletion

of intracellular pools of APOBEC3G and 3F, Vif prevents the incorporation of these proteins into virions, thereby subverting their antiviral activity.

Vif is important for the replication of FIV, SIV, and HIV in most cultured cells. Mutations that knock out the *vif* open reading frame of FIV drastically reduced viral replication.³⁰³ SIVmac239 with a deletion in the *vif* gene was produced in a *vif*-complementing cell line and inoculated into monkeys.⁶⁹ Inoculated animals showed no plasma antigenemia, no recoverable virus, and no SIV sequences in peripheral blood detectable by PCR. However, inoculated monkeys did develop a low-level antibody response. Thus, SIV Δ vif does appear to be infectious for rhesus monkeys, but it is the most highly attenuated strain yet studied. Similarly, knockout of the *vif* gene in FIV resulted in a high degree of attenuation even for newborn kittens.³⁰⁹

Nef

All of the primate lentiviruses, but not the nonprimate lentiviruses, have a *nef* gene (Tables 51.4 and 51.5). The 5' end of SIVmac *nef* overlaps the *env* reading frame, whereas no such overlap exists for the *nef* gene of HIV-1. Although there is correspondence in sequence for most of SIVmac Nef and HIV-1 Nef, SIVmac Nef is approximately 40 to 50 amino acids longer due to additional N-terminal sequences; these extra sequences appear to have no homologs in HIV-1 *nef*. Nef is not essential for virus replication but is important for efficient virus replication *in vivo*.¹⁶⁴ A multitude of functional activities have been attributed to Nef. These include but are not limited to: the downregulation of CD4, MHC class I and the TCR; lymphocyte activation; infectivity enhancement; and antagonism of tetherin/BST-2. HIV-1 and SIV Nef both downregulate CD4 to prevent engagement by Env on nascent virions.¹⁰⁰ Likewise, HIV-1 and SIV Nef both selectively downregulate certain MHC class I molecules to evade the recognition of infected cells by virus-specific CD8⁺ T cells, while leaving others on the cell surface to inhibit NK cell activation.^{47,68,329} However, the residues that contribute to MHC class I downregulation differ for HIV-1 and SIV Nef.³³⁰ In HIV-1 Nef, these sequences are located near the N-terminus of the molecule, whereas in SIV Nef these sequences map to the C-terminus.³³⁰ For SIVsmm/mac, HIV-2, and most other primate lentiviruses, with the possible exception of HIV-1 and SIVgsn/mon/mus, Nef downregulates the TCR through interactions with the TCR ζ chain.^{135,295} TCR downmodulation reduces the sensitivity of infected CD4⁺ T cells to activation and has been proposed to contribute to the non-pathogenic nature of SIV infection in natural hosts.²⁹⁵ An additional role for Nef in lymphocyte activation was revealed by the observation that the replication of *nef*-deleted SIV in an immortalized T-cell line was IL-2-dependent, whereas the replication of wild-type SIV, and recombinants expressing HIV-1 *nef* alleles, was not.³ Nef also enhances the infectivity of HIV-1 and SIV by a poorly understood mechanism that involves binding to Dyn2.^{44,266} In addition, the Nef proteins of most SIVs, with the exception of SIVgsn/mon/mus, counteract restriction by the tetherin proteins of their nonhuman primate hosts.^{149,289,382} This activity is dependent on a five-amino-acid sequence that is present in the cytoplasmic domain of the tetherin orthologs of apes and Old World monkeys, but is missing from human tetherin,^{149,382}

and appears to involve the downmodulation of tetherin from sites of virus release at the cell surface.¹⁴⁹

The properties of SIV strains with mutations in *nef* have been extensively studied. SIVmac239 with an in-frame stop at codon 93 of *nef* uniformly reverted to an open *nef* reading frame by 2 weeks after monkey infection.¹⁶⁴ Even a form of SIV with a four-amino-acid deletion in *nef* has reverted in about 10% of infected monkeys.³⁶⁴ So there is strong selective pressure to maintain an open *nef* reading frame. SIV with deletions in the *nef* gene are markedly attenuated compared with parental virus. Viral loads are typically reduced by two to three logs at the time of peak viremia, 2 weeks after infection and ≥ 3 to 4 logs at set point. Most monkeys infected with SIVmac239 Δ *nef* have survived without disease and with undetectable viral loads for as long as they have been studied. Despite the marked attenuation, infection with SIVmac239 Δ *nef* is clearly persistent, only at much lower levels. From 10% to 20% of monkeys infected with SIVmac239 Δ *nef* have gone on to develop moderate viral loads and to develop AIDS despite the absence of the *nef* gene. Serially passaged Δ *nef* SIV has shown a consistently pathogenic phenotype, and compensatory changes elsewhere in the genome appear to be responsible.⁴ Sequence changes in the cytoplasmic domain of gp41 of serially passaged *nef*-deleted SIV have been definitively shown to restore the virus's ability to counteract tetherin.³⁰² *Nef*⁻ SIV replicates similarly to wild-type SIV in a variety of standard cell-culture systems, including lectin-stimulated PBMC cultures supplemented with IL-2, although conflicting reports have appeared.

The attenuated properties of SIV Δ *nef* in monkeys appear to be similar to what has been observed in unusual cases of *nef*⁻ HIV-1 infection in humans. One human in the United States has been consistently infected with an HIV-1 with large deletions in *nef* since 1983.¹⁶⁸ In Australia, a blood donor with *nef*-deleted HIV-1 was responsible for infecting eight recipients; the donor and recipients have been slow or nonprogressors with low or undetectable viral loads.⁶⁷ *Nef*-deleted HIV-1 is clearly an attenuated virus with a level of attenuation similar to that of SIVmac Δ *nef*. However, as with monkeys infected with SIVmac Δ *nef*, some of the humans infected with HIV-1 Δ *nef* show signs of disease progression.^{114,181,379}

An unusual *nef* allele (YE *nef*; PBJ14 *nef*) has an ITAM that results in the ability to stimulate lymphocyte activation and to cause an unusually acute disease⁸¹; no analogous HIV-1 *nef* allele has been found.

Vpr and Vpx

Whereas all known primate lentiviruses contain a *vpr* gene, the *vpx* gene is present in only the SIVsm/mac/HIV-2, SIVrcm and SIVmnd2 lineages. *Vpr* and *vpx* are related by ancestral gene duplication and encode proteins with similar amino acid sequences. Moreover, Vpr and Vpx are both incorporated into virions through specific interactions with sequences in the p6 domain of p55 Gag. However, the activities of these accessory proteins differ. Vpr induces G₂/M cell-cycle arrest and apoptosis in infected cells,^{123,158,273,280} and has been implicated in the nuclear import of the preintegration complex in nondividing cells.⁹⁰ In contrast, Vpx is required to overcome an early block to the infection of macrophages and dendritic cells that occurs prior to the completion of reverse transcription.^{90,113,304} Both proteins associate with the Cul4^{DDB1/DCAF1} ubiquitin ligase complex by binding to VprBP1 (DCAF1) and are thought to

mediate the proteasomal degradation of specific cellular proteins.^{136,179,299,327} While the target of Vpr remains to be identified, Vpx-mediated degradation of SAMHD1 was recently shown to alleviate a block to reverse transcription in macrophages and dendritic cells.^{137,177} SAMHD1 is a deoxynucleotide triphosphohydrolase that inhibits reverse transcription in myeloid cells by depleting cellular dNTP pools. Thus, SAMHD1 imposes a block to HIV-1 infection of macrophages and dendritic cells that is overcome by Vpx.

Two lines of evidence indicate that *vpr* is not a major contributor to the replication of SIVmac in experimentally infected rhesus monkeys. SIVmac239 with a stop signal in the initiating ATG codon of *vpr* was slow to revert.¹⁷⁸ SIVmac239 with a deletion in *vpr* replicated only slightly less efficiently than did parental virus in rhesus monkeys, and all *vpr*⁻ SIV infections in animals have progressed to AIDS.¹⁰⁶ The effects of deleting *vpx* from SIVmac239 on levels of replicating virus in rhesus monkeys were more significant; nonetheless, more than half of such monkey infections progressed to AIDS.¹⁰⁶ A *vpx* deletion of SIVsmPBJ14 was strongly outcompeted when co-inoculated with parental virus,¹³⁰ consistent with these results. Deletion of both *vpr* and *vpx* markedly attenuated the virus, resulting in a virus that was about as attenuated as SIVmac239 Δ *nef*.¹⁰⁶

Env

Env is essential for virus replication. The protein products of the *env* gene are responsible for binding receptor(s) on the cell surface and mediating virus entry into cells. The products of *env* are the major or only targets of antibodies that can neutralize infectivity. Determinants of the differences in tropism of related viruses thus often map to the *env* gene. Whereas SIVmac replicates well in stimulated PBMCs from macaques, HIV-1 replicates not at all or only very poorly in macaque cells. Surprisingly, the block to replication of HIV-1 in macaque cells maps outside of the *env* gene.³¹¹ The restricting element TRIM 5 α may be overcome by changes in gag sequence.³²⁸ Derivatives of SIVmac, in which the *env* gene has been replaced by *env* of HIV-1, are replication competent in macaque cells and capable of infecting monkeys.^{142,188,203,310} Serial passage of several second-generation SHIVs has resulted in strains that are consistently pathogenic in macaques (see previous section on Clinical and Pathologic Features: Simian Immunodeficiency Virus).

U3

The U3 regions of the primate lentiviruses are unusually long compared with their counterparts in the nonprimate lentiviruses.¹⁴⁴ Most of this unusual length can be accounted for by the overlap of *nef* coding sequences with the LTR. In fact, several lines of evidence suggest that about 300 base pairs (bp) of U3 sequence in SIV and HIV may be nothing other than *nef* coding sequence.

1. In monkeys infected with SIV missing 182 bp in the region that is uniquely *nef*, the SIV progressively and consistently loses about 300 bp of sequence in the region of U3–*nef* overlap.¹⁶⁹ The 12 terminal nucleotides of U3 are consistently retained because these are needed for integration. About 50 bp at the C-terminus of *nef* coding sequence, immediately upstream of the nuclear factor- κ B NF- κ B site, are also consistently retained; this region is known to contain a poorly characterized enhancer element.^{143,212,268}

2. In a human infected with a *nef*-deleted variant of HIV-1, sequences in the U3–*nef* region also were progressively lost over time.¹⁶⁸ Again, the U3 terminal nucleotides and 50 bp upstream of the NF- κ B site were consistently retained.
3. The 300-bp region of *nef*–U3 overlap has been grossly altered in SIVmac239 by 102-point mutations without changing the predicted amino acid sequence of the encoded Nef protein.¹⁴⁴ This virus replicated like wild-type virus in rhesus monkeys without evidence of specific reversional events through at least 20 weeks of infection.

These results are most easily explained whereby these 300 bp of U3 sequence serve predominantly or exclusively as *nef* coding sequence. However, it also is possible that this region contains transcriptional control elements that respond to factors induced by *nef* or that in the absence of *nef*, any transcriptional control elements in this region provide less-selective advantage than does a shorter genome.

NF- κ B and Sp1

Sequence elements in U3 for binding NF- κ B and Sp1 transcription factors have been defined as major enhancer elements of HIV-1, HIV-2, and SIV. However, SIVmac is still able to replicate well in a variety of cell types in the complete absence of NF- κ B and Sp1 elements.¹⁴³ This is due predominantly or exclusively to an enhancer element present within the 50 bp immediately upstream of the NF- κ B element within sequences that are also *nef* coding sequences.^{143,212,268} SIVmac239 derivatives with the NF- κ B sites removed from both LTRs or with all Sp1 sites removed from both LTRs were not detectably attenuated in rhesus monkeys.¹⁴³ SIVmac239 with NF- κ B and Sp1 sites removed was detectably attenuated, but not markedly so.¹⁴⁵ HIV-1 replication appears more heavily dependent on the presence of the NF- κ B and Sp1 sites,²⁸⁵ but circumstantial evidence suggests an enhancer element within the 50 bp upstream of the NF- κ B binding sequence in HIV-1 as well.¹⁶⁸ This enhancer element remains poorly characterized. Evidence has been presented suggesting that this short stretch immediately upstream of the NF- κ B binding region may contain AP1 and C/EBP elements in HIV-1 and AP1 and PUB elements in SIVmac and HIV-2.¹⁶⁷

Multiply Deleted Derivatives

Work in the SIV system has shown that virtually any level of attenuation can be achieved simply by varying the number and locations of deletion mutations.⁶⁹ Attenuation has been scored by measure of viral load at peak, viral load at set point, strength of the antibody response, and propensity to induce declines in the numbers of CD4⁺ lymphocytes. Lack of viral persistence is a phenotype that has never been consistently associated with any mutant strain.

Genetic Resistance

Although individual examples of resistance to disease occur throughout the lentivirus subfamily, the clearest documentations of mechanisms by which it can occur come from studies with humans. In humans, decreased susceptibility to HIV-1 disease is associated with co-receptor polymorphisms, MHC class I alleles, KIR alleles and with chemokine gene dosage (see Chapter 50). In humans, disease progression is uniformly related to virus load, with high loads being of poorer prognosis and low loads being of better prognosis.

As in humans, certain MHC class I alleles have been associated with the control SIV infection in rhesus macaques. *Mamu* (*Macaca mulatta*)-A*01, a common MHC class I allele present in 22% of Indian-origin rhesus macaques, is associated with a fivefold reduction in chronic phase plasma viral loads.²³⁰ *Mamu-B*08* and *-B*17*, present in 6% and 11% of Indian-origin rhesus macaques, respectively, are significantly overrepresented among elite controllers (animals that contain plasma viremia below 1,000 copies/ml).^{199,374} The protective effect of *Mamu-B*08* is particularly strong, and is associated with more than a sevenfold reduction in chronic phase viremia.¹⁹⁹ However, the protective effect of *Mamu-B*17* is less clear, since viral loads in *Mamu-B*17*–positive animals vary considerably, possibly reflecting a role for other genetic loci.³⁷⁰ Interestingly, *Mamu-B*08* binds a very similar set of peptides as HLA-B*2705, a molecule associated with the control of HIV-1 replication in humans, suggesting that the peptides bound by these molecules are related to their ability to suppress virus replication.²⁰⁰ Although the mechanisms by which these MHC class I alleles lead to the containment of virus replication remains to be fully defined, evidence from CD8-depletion and CTL escape points to a role for CD8⁺ T cell responses.

As discussed earlier in this chapter, *TRIM5* polymorphisms are also associated with differences in the ability of rhesus macaques to control certain strains of SIV. *TRIM5Cyp* and TFP_{339–341} variants of *TRIM5 α* potentially inhibit the replication of SIV_{sm}E543-3, and probably the closely related strain SIV_{sm}E660, due to the incomplete adaptation of the capsid proteins of these viruses for resistance to rhesus macaque *TRIM5* proteins.¹⁷⁰ The differential susceptibility of SIV_{sm}E543-3 and SIV_{sm}E660 to variants of *TRIM5* is a significant factor in the interpretation of vaccine studies in rhesus macaques using these challenge viruses.

A striking example of a genetic polymorphism with analogies to the human situation has been documented in red-capped mangabeys. A 24-bp deletion (Δ 24) was noted in the *CCR5* gene of red-capped mangabeys with an allelic frequency of 86.6%.⁴⁰ Eleven of 15 red-capped mangabeys were found to be homozygous for this polymorphism. Interestingly, the SIV from red-capped mangabeys does not use *CCR5* as co-receptor but is unusual in its predominant use of *CCR2b* as co-receptor.

A prominent place to look for mechanisms of disease resistance other than in humans is in sooty mangabey monkeys and African green monkeys. These species are naturally infected with their own SIV without disease, and there is clearly no problem with the SIV that they carry because their SIVs are capable of causing AIDS when transmitted to Asian macaques. Based on experience with HIV-1 in humans, one would expect viral loads in sooty mangabeys and green monkeys to be low. Surprisingly, this is not the case. As discussed previously in the Virulence section, many sooty mangabey monkeys and African green monkeys carry SIV RNA loads in plasma in a range (10²–10⁶ copies/mL) in which disease progression uniformly occurs with HIV-1 in humans and SIV in macaque monkeys.^{30,108,160,276} The mechanisms of disease resistance in these species remain to be elucidated, but are likely to relate at least in part to an ability to resist chronic lymphoid activation (see Virulence section above) and may also relate in part to polymorphisms in co-receptor genes as suggested by the recent discovery of a high prevalence of defective *CCR5* alleles in the sooty mangabey.

An allele of *CCR5* with a 2-base pair deletion (*CCR5* Δ 2) that prevents *CCR5* expression on the cell surface was

recently identified in sooty mangabeys. This allele is present at a frequency of about 26% in sooty mangabeys; together with another allele with a 24-bp deletion (*CCR5* $\Delta 24$) present at a frequency of about 3%, it is estimated that nearly half of all sooty mangabeys are either homozygous (8%) or heterozygous (41%) for defective alleles of *CCR5*.²⁷⁹ Yet, SIVsmm is fully infectious for primary CD4⁺ lymphocytes from CCR5-null animals and is insensitive to the CCR5 antagonist maraviroc.²⁷⁹ An analysis of the ability of SIVsmm to infect cells expressing CD4 together with alternative co-receptors revealed that the virus could use GPR15, CXCR6, and to a lesser extent GPR1, but not CXCR4, CCR3, CCR8, or CCR2b.²⁷⁹ The inability of SIVsmm to use CCR2b as a co-receptor was surprising given that SIVrcm has been shown to preferentially use CCR2b as a co-receptor in red-capped mangabeys due to the high frequency of the *CCR5* $\Delta 24$ allele in this species.⁴⁰ While the co-receptor(s) used for SIVsmm infection *in vivo* remain to be defined, these results suggest that the cellular tropism of this virus is determined by a co-receptor other than CCR5. Thus, it will be important to define the cellular targets of SIVsmm infection in sooty mangabeys to determine if they are less susceptible to viral turnover or less critical for immunologic function in ways that might reconcile high levels of persistent virus replication with the lack of chronic lymphoid activation and the lack of disease progression in this species.

DIAGNOSIS

Because lentiviral infections are persistent, antiviral antibodies are present throughout the lifetime of the infected host. Detection of antiviral antibodies is thus the most widely used method for determining the presence of viral infection. A variety of methods are commonly used for antibody detection that vary with the individual virus. These include enzyme-linked immunosorbent assay (ELISA), Western blot, gel diffusion, indirect immunofluorescence, hemagglutination, complement fixation, and neutralization assays. The commonly used Coggins test for the detection of EIAV infection is a gel-diffusion assay for the detection of antiviral antibodies. Attempts are being made to develop simpler ELISAs for EIAV and other nonprimate lentiviruses. ELISA assay methods for the detection of antibodies to FIV are now routinely available. However, a partially efficacious vaccine for FIV is also now in use, which can complicate detection of infected cats. ELISA is most commonly used for the detection of antibodies to SIV; detection by ELISA is usually routine but can be complicated by the history of the monkey, whether the antibodies are to the same or a different type of SIV (i.e., cross-reactive), and, in an experimental setting, the presence of antibodies at low levels due to attenuation or intervention. Positivity can be confirmed by virus isolation or by identification of viral antigens or viral RNA in plasma or cells. The presence of specific clinical signs and clear demonstration of the presence of antilentiviral antibodies is usually sufficient for a definitive diagnosis.

PREVENTION AND CONTROL

MVV was eradicated from Iceland by a drastic slaughter policy before the availability of diagnostic tests. Test and removal pro-

grams have since been and continue to be used as an effective means of control. Test and removal programs may be voluntary or mandated. Buyers of horses have increasingly sought negative test certification for EIAV, and negative test certification is required as a condition for entry into many racetracks, salesyards, and shows. Horses imported into the United States and some other countries are required to have a negative test certificate. Testing within a state is not always compulsory, nor is it compulsory for an owner to destroy a positive horse. For FIV, testing is routinely available for cats under veterinary care and animals in shelters are also routinely screened. However, test and removal programs and certification at the point of sale have been sparingly applied to FIV.

Two vaccines are currently used in the field for the prevention of lentivirus infections. A live attenuated EIAV strain was developed by researchers by repeated passage in donkey cells.³⁰⁸ This EIAV vaccine has been extensively used in China, where it has been administered to millions of horses with apparent safety and efficacy, and in Cuba. Unfortunately, little is known in the western world about the properties of this live attenuated vaccine, its genetic composition, or details regarding its performance in the field. Sequences from Chinese EIAV vaccine strains have recently been published; an accumulation of nucleotide substitutions, not deletions, appears to be the basis for attenuation.³⁵⁹ EIAV vaccine virus derived from a single proviral clone did not fare as well in vaccine challenge experiments as the actual vaccine, which contains extensive sequence diversity.²⁰⁴ The second vaccine now in use is against FIV, initially developed using whole-infected cells as immunogen, then subsequently using killed cell-free virus preparations as a mixture of representatives from two distinct clades.²⁷¹ Efficacy in prevention of experimental FIV infections has been reported as 85%, which is less than desired but substantially better than reported for efficacy trials of HIV vaccines, at least to date.

RESEARCH ON VACCINE DEVELOPMENT

One important application of research with nonhuman lentiviruses is in the area of vaccine development. Certainly, development of a safe, effective, affordable vaccine for AIDS is one of the greatest challenges of our time. Most experimental studies have used SIV in rhesus monkeys. Use of SHIV in rhesus monkeys has also been extensively used because it allows analysis of HIV-1 *env*-containing vaccine products in a system in which challenge and meaningful viral load and disease readouts are readily possible.

Expectations were raised when inactivated whole SIV was found to provide protection against pathogenic strains of SIV.^{73,232} Hope was quickly dashed, however, when it was found that protection occurred only when the vaccine and challenge stocks were grown in human cells.^{57,58} When the vaccine was prepared in human cells and the challenge virus was grown in monkey cells, protection was not observed. Xenoantigens present in virus preparations were able to confer protection when a challenge virus was grown in the same xenogeneic cells. MHC class II was reported to be at least one of the xenoantigens capable of conferring protection.¹⁰ MHC class II antigens may actually be present in greater abundance in virus particles than the virus-encoded envelope proteins.⁹ The mechanisms by which antibodies to MHC class II present on the surface of

virus particles can block viral infection have not been defined, but it could be as simple as steric hindrance. Improved methods for purifying, inactivating, and delivering whole particles justify continued investigation of this vaccine approach.²⁸⁶ Whether the abundance of MHC class II antigens on virus particles has significance for pathogenesis remains to be determined.

Vaccine studies in animal models can provide useful information in several ways. Head-to-head comparisons of different vaccine approaches can shed light on which approaches perform more effectively, at least under the defined conditions of the experiments. In-depth analyses of individual vaccine approaches also may provide fundamental insights into immunologic control and what is needed for protective immunity. With these goals in mind, vaccine approaches that have been tried in animal models include a variety of envelope subunit approaches; poxvirus recombinants; DNA; inactivated whole particles; adenovirus recombinants; vesicular stomatitis virus recombinants; and prime and boost protocols that use combinations of these approaches. Several themes arising from these studies are worth noting.

1. The particular virus that is used for challenge is one of the single most important determinants of whether an individual vaccine challenge study will be successful. Easy-to-neutralize, nonpathogenic strains of virus have proven relatively easy to protect against. Difficult-to-neutralize pathogenic strains of virus, which could be considered representative of field strains of HIV-1, have proven very difficult to protect against. A homologous cloned virus challenge is less stringent than a closely matched uncloned virus challenge, which in turn is much less stringent than a challenge by a virus with natural, representative levels of sequence divergence. It has proven easy to prevent the acute disease course resulting from CXCR4-tropic SHIV infections using a variety of vaccine approaches.
2. Timing of the challenge is crucial. The vaccine approaches discussed earlier induce transient immune responses; they decay dramatically after the peak of vaccine-induced immune responses, which occurs within the first few weeks after the last vaccine boost. Most challenge experiments have been performed 2 to 4 weeks after the last vaccine boost.
3. It may be easier to achieve protection against a mucosal challenge than against an intravenous challenge. Most early studies used intravenous challenge because of the ability to achieve infection reproducibly in control monkeys with carefully controlled doses of challenge virus. Many studies now use vaginal or rectal mucosal challenge because these routes model the major modes of HIV transmission around the world. Repeated low-dose mucosal challenge models have also been developed.
4. Antibody responses to the envelope glycoprotein and cellular responses to core Gag–Pol antigens can contribute to protection. Which type of immune response can be most responsible for protection varies with the vaccine approach and characteristics of the challenge virus. Inclusion of SIV *gag-pol* and *env* in recombinant poxviruses resulted in improved protection in a vaccine/challenge format compared with when either *gag-pol* or *env* was used alone.²⁶⁹
5. When pathogenic, difficult-to-neutralize SIV strains have been used for challenge, protection has proven difficult to achieve with the vaccine approaches that have been tried to

date. Even when using a challenge virus identical or highly similar in sequence and challenge 2 to 4 weeks after the last vaccine boost, the levels of solid long-term protection by any criteria have seldom reached even 50%.

Live attenuated strains of SIV have performed more impressively as vaccines in experimental monkey studies.⁶⁰ Although the live attenuated vaccine approach is not under any serious consideration for practical development for use in humans, continued studies hope to identify critical components of a protective immune response and critical variables that may influence whether a protective immune response is attained. For example, it has been learned that a wide range of attenuation can be achieved by varying the number and location of deletion mutations.⁶⁹ Some strains—for example, SIVmacΔ4 (missing *vpr*, *vpx*, *nef*, and U3 sequences) and SIVΔkRXN (missing NF-κB, *vpr*, *vpx*, and *nef*)—are highly attenuated but still persist. SIVΔvif is so highly attenuated that infection is undetectable by standard criteria. In general, the ability to achieve protection varies inversely with the degree of attenuation. Thus, more highly attenuated strains are safer but less protective as vaccines.¹⁵⁵ Protection is also time dependent; a protective state can take 6 months or longer to become established. An understanding of protective immunity by live attenuated strains will require an explanation of why it takes so long to develop. Even the live attenuated vaccine strain SIVmac239Δ3 (missing *vpr*, *nef*, and U3 sequences) provides only minimal protection against heterologous challenge with SIVsmE660, which contains a level of sequence divergence that one would expect to encounter with a field strain of virus.³⁷¹ Although this difficulty could conceivably be addressed by using mixtures of sequences in the vaccine strain, the results illustrate the major hurdles that must be overcome to achieve protection against pathogenic, difficult-to-neutralize strains of SIV.⁷¹

The potential of adeno associated virus (AAV) for the delivery of antibodies with potent broadly neutralizing activity as a preventative has been nicely modeled in monkey studies.¹⁵⁴

RESEARCH ON THERAPEUTIC REGIMENS

Antiviral drugs useful against HIV-1 in humans have been developed with little or no input from animal models of lentiviral infection. This trend will likely continue. However, there is a growing realization that study of certain types of therapeutic intervention in model systems can provide valuable information. Cytokines, immunoadjuvants, immune stimulants, immune suppressants, or other highly experimental treatments that could possibly be harmful in the setting of a lentiviral infection can be examined for possible benefit in animal models. Faced with several possible lead compounds, some companies have chosen head-to-head comparisons in an animal model to help select the most promising compound to move forward. Comparisons of experimental regimens during primary infection, analysis of ways to boost virus-specific CD4⁺ T-helper cell responses during therapy, and analysis of ways to minimize maternal–infant transmission are also areas in which ongoing work in animal models may provide useful information to help guide trials of therapeutic regimens in humans.

Some of the antiviral drugs useful against HIV-1 have reduced or marginal activity against SIV. Überla et al.³⁴¹

generated an RT–SHIV in which the RT reading frame of SIVmac239 has been replaced by that of HIV-1. This RT–SHIV needs adaptive changes for optimal replication^{7,320} and is capable of inducing disease in monkeys.³⁴¹

PMPA (*R*-9-2-phosphonylmethoxypropyl adenine) is one compound with strong antiviral activity against both HIV-1 and SIV that has been used extensively in monkey studies. Tsai et al.³³⁸ were the first to show that treatment of monkeys with PMPA by 24 hours after SIV inoculation and continuing treatment for 4 weeks prevented the establishment of a persistent infection. Delaying the initiation of therapy to 48 or 72 hours or shortening the duration of treatment significantly reduced efficacy.³³⁷ Nonetheless, even when the establishment of persistent infection was not prevented, early treatment significantly reduced viral loads and prolonged AIDS-free survival.^{337,348}

In another study,¹⁹⁴ monkeys were started on PMPA therapy 24 hours after inoculation of SIVsm E660 and kept on the therapy for 28 days, similar to the studies of Tsai et al.³³⁷ and van Rompay et al.³⁴⁸ Establishment of a detectable, traditional, persistent infection was prevented, confirming the results of Tsai et al. A low-level, controlled infection was demonstrated, however, since CD8⁺ cell depletion resulted in the emergence of readily detectable virus.¹⁹⁵ Interestingly, when three such animals off therapy for 6 weeks were subsequently challenged intravenously with SIVsm E660, one animal was completely protected, and the other two showed dramatic reductions in viral load.¹⁹⁵ What is most startling and difficult to understand is that protection has been achieved in some animals in the absence of readily measurable SIV-specific antibody or cellular responses at the time of challenge. Continuation of this line of investigation promises important new insights into immune-mediated control outside the bounds of our current level of understanding.

Hematopoietic stem cell gene therapy is an attractive, futuristic approach for the prevention of HIV-induced disease, but it is clear that many developmental hurdles must be cleared. Research with SIV in monkeys is proving useful toward this goal. Transduction of CD34⁺ hematopoietic progenitor cells with an anti-*tat* gene protected T-cell and macrophage progeny from SIV infection.²⁸⁴ Infusion of lymphocytes with antisense *tat/rev* genes into macaques may have reduced SIV replication on subsequent SIV inoculation.⁷⁷

PERSPECTIVE

The worldwide crisis brought on by HIV and AIDS has focused attention on the nonhuman lentiviruses as a source for information that will shed light on the human condition. Lentiviral infections of domesticated animals are economically important in their own right and have been studied historically in this context. The lack of a reliable, usable animal model that uses HIV-1 itself and that recapitulates the features of human infection has resulted in extensive study of nonhuman lentiviruses as analog models in which susceptible hosts are infected with nonhuman lentiviruses, either naturally or experimentally. The most critical issues for future progress include better understanding of pathogenesis; improvements in therapy; improved availability of therapy; and, perhaps most important, development of a safe, effective, affordable vaccine. The most remarkable feature of these viruses, and perhaps most critical for the eventual control of HIV, is their ability to replicate continuously and unre-

lently despite apparently strong immune responses. Further advancement of therapeutic regimens and development of effective vaccines against HIV will have to deal with the strategies of immune evasion used by this group of viruses.

Perspectives

The name *foamy virus* (FV) was coined in the 1950s to acknowledge the spontaneous emergence of the typical foamy cytopathic effect (CPE) produced in response to FV infection (Fig. 52.1A). This is characterized by multinucleated syncytia and vacuolation in primary monkey kidney cultures leading to a “foamy” appearance.^{47,154,186,206} Subsequently, it was found that CPE development was attributed to the fact that the monkeys were latently infected with a transmissible agent. Following the discovery of reverse transcriptase, the transmitted agent was shown to be a retrovirus.¹⁷² The first 30 years of FV research dealt mainly with the identification of infected monkeys, prior to sacrifice, as sources of primary cell cultures. Molecular cloning of the first FV—at that time believed to be a human isolate—permitted functional studies on the replication of FVs.¹⁹² FV research gained momentum following

the discovery that these viruses replicate differently from all other retroviruses.^{133,264} This culminated in the finding that the FV infectious genome appears to be DNA rather than RNA.^{160,203,269} In brief, the FV replication strategy combines those of retroviruses with some characteristics of hepadnaviruses, such as hepatitis B virus (HBV), with other properties that are unique to FVs.^{120,186,190} In virtually any aspect that has been examined, FVs replicate differently from all other retroviruses. This has led to the definition of two retroviral subfamilies, the *Orthoretrovirinae*, which encompass all retrovirus genera except FVs, and the *Spumaretrovirinae*, which constitute only the spumaviruses or FVs.¹³⁴ This chapter will summarize what is known about the biology of these viruses; for reviews on particular aspects, such as FV vectors, the reader is referred to more specialized reviews.^{132,188,246,249} We shall focus on FVs of primates and mention the nonprimate viruses only when they become relevant.

FOAMY VIRUS ISOLATION AND DIAGNOSIS OF INFECTION

FV isolation is relatively easy on primary fibroblasts from throat swabs, although any other tissue as source of virus can be used.^{94,154,166,186} Virus isolation from peripheral blood lymphocytes is greatly enhanced by the addition of anti- γ -interferon (γ -IFN) antibodies.⁵⁶ A virus isolate displaying the typical giant cells’ CPE (Fig. 52.1A) can be confirmed by the detection of reverse transcriptase activity, by immunofluorescence assay (IFA) demonstrating a predominantly nuclear antigen (Fig. 52.1B), or by nucleic acid detection methods.^{94,154,166,186,222}

The diagnosis of an FV infection can be made by demonstrating antibodies against the main structural proteins (typically the Gag doublet, see later discussion) in serologic assays,⁷¹ such as immunoblots or radioimmunoprecipitation assays (Fig. 52.2). The choice of the right antigen in these assays is important, because the reaction is, at least in part, virus type specific.^{96,102,112} To verify an FV infection, the serologic analysis should be combined with nucleic acid detection methods (typically polymerase chain reaction [PCR]). For this, the amplification of a conserved (~420 bp) fragment from the integrase (IN) domain of the *pol* gene has proven to be extremely useful.²²⁰

NATURAL HISTORY AND *TRANS*-SPECIES TRANSMISSIONS

Various vertebrate species are naturally infected with FVs. Table 52.1 and Figure 52.3A give an overview of some isolates.

FIGURE 52.1. A: Multinucleated giant cell cytopathic effect induced by a primary monkey foamy virus (FV) isolate on baby hamster kidney 21 (BHK-21) cells. **B:** Typical nuclear fluorescence of a primary monkey FV isolate grown in human fibroblastoid cells reacted in indirect immunofluorescence assay with homologous serum. (With kind permission from Springer Science+Business Media: Neumann-Haefelin D, Rethwilm A, Bauer G, et al. Characterization of a foamy virus isolated from *Cercopithecus aethiops* lymphoblastoid cells. *Med Microbiol Immunol* 1983;172:75–86.)

In addition to FVs of Great Apes,^{94,95,154,186} Old and New World simians,^{94,154,186} and prosimians,^{99,154,186} FV infections appear to occur worldwide in bovines and other *Artiodactyla*,^{5,59,148,149a,154,186} equines,^{119,154,186,242} and felidae.^{154,186,196} Whether sea mammals are natural hosts has not been intensively investigated.^{110,154,186} Probably all monkey species harbor an FV.^{94,100,135,154,186} Prevalence in the natural host in the wild may be as high as 100% and is usually more than 30%.^{94,135,154,186} It is therefore not unlikely that FVs are, in terms of prevalence, the most successful of all retroviruses. Although host restriction factors show some species restriction (see later discussion), FVs have been reported to cross the species barrier between monkeys and apes in captivity or in the wild.^{94,124,135} In their hosts, FVs cause lifelong persistent infections of a benign nature, often in the presence of neutralizing antibodies.^{94,154,186} Laboratory animals, such as mice and rabbits, have also been infected in the absence of overt disease.^{26,93,94,208,214}

Humans are not a natural host of FVs.¹⁸⁶ Indeed, the best-studied FV was once believed to be of human origin.^{1,143} It has now been designated as the prototype foamy virus (PFV).¹⁸⁷ Ini-

FIGURE 52.2. Radioimmunoprecipitation analysis of metabolically ³⁵S-Met/Cys labeled 293T cell lysates transfected with a prototype foamy virus (PFV) proviral expression construct (lane 1, PFV) or empty expression vector (lane 2, mock) using foamy virus–positive chimpanzee serum. The immunodominant viral proteins precipitated by this serum are indicated as well as the molecular weight markers (on the right).

tial reports on naturally occurring human infections^{144,147} were not confirmed by the large-scale screening of more than 5,000 samples using sophisticated methods such as a combination of antibody detection and PCR.^{2,222} Furthermore, postulated associations of FVs with human disease states, mainly autoimmune disorders and neurologic diseases of unknown origin could not be validated.^{40,86,201,223} Because of the close nucleotide sequence homology to FVs from the *Pan troglodytes schweinfurthii* chimpanzee *sub*-species,^{88,135} the single human isolate from a Kenyan patient is now believed to have resulted from a *trans*-species transmission of a virus from these chimpanzees that were once more prevalent in East Africa.⁵¹ Primate FVs are currently not circulating in the human population. However, humans are susceptible to zoonotic transmissions of nonhuman primate (NHP) FVs.^{218,232} Altogether, around 100 human infections with NHP FVs have been confirmed worldwide. In a survey, the Centers for Disease Control and Prevention identified approximately 2% seropositives and virus DNA positives among several hundred samples from occupationally to NHP-exposed persons and could isolate virus in several instances.^{22,87} Some of these

PFV, prototype foamy virus; SFV, simian foamy virus; n.a., not available; FFV, feline foamy virus; BFV, bovine foamy virus; EFV, equine foamy virus; SHFV, sheep foamy virus; SLFV, sea lion foamy virus.

FIGURE 53.3. A: Phylogenetic relationship of complete foamy virus *pol* gene sequences from various isolates. **B:** Phylogenetic relationship of some human infections to the transmitted simian foamy viruses based on a conserved approximately 420-bp integrase gene fragment of the *pol* gene. To simplify matters, human infections were named consecutively after the original virus (in bold); they cluster with the viruses of the transmitting ape or monkey species. For **A** and **B**, evolutionary distances are indicated as nucleotide substitutions $\times 100$ and were calculated with 10,000 bootstrap trials. (Courtesy of J. Bodem, Würzburg, Germany.)

infections date back decades and were the result of severe monkey bites.^{22,87} FV infection has also been identified in African bushmeat hunters.³⁰ Other persons at risk are those living in close proximity to quasi-wild NHPs (e.g., at Asian temple sites) or individuals possessing an NHP pet.¹⁰¹ A very special case may be human recipients of NHP xenotransplants.⁴ Human infections are lifelong; however, none induced any disease and remained unrecognized prior to the investigation. The viral load in buffy-coat cells of infected humans revealed a very low number of FV DNA copies.³⁰ Moreover, in contrast to lentiviruses, *in vivo* adaptation to what can be called a human FV has not occurred. Even after decades of infection, FVs in humans have remained relatively unchanged at the nucleotide level, and the transmitting donor species can be readily identified^{22,87} (i.e., a baboon FV will remain a baboon FV even after decades in a human host) (Fig. 52.3B). Although the sample size is relatively small, there is no indication of human-to-human transmission even between close contacts.^{22,64a} Because FV can be transmitted by transfusion,^{25,111} infected persons have been advised not to donate blood to avoid new human retrovirus infections.⁸⁵

For reasons that are not fully understood, men appear to be a “dead-end” host for primate FVs. With respect to human infections by non-NHP FVs, it is worth mentioning that the antibody screening of more than 200 veterinarians at risk of acquiring a feline foamy virus (FFV) infection did not reveal a single positive case.²⁸ Based on this result, it appears unlikely that bovine or equine foamy virus (BFV and EFV, respectively) can infect humans. However, this has not been thoroughly investigated.

EVOLUTION OF FOAMY VIRUSES

Exogenous FVs are very ancient retroviruses. Exogenous FVs are very ancient retroviruses. There exist three examples of endogenous FVs, which suggest that exogenous FVs were around before that times: 1) Katourakis et al.¹⁰⁸ reported the detection of endogenous FVs (SloEFV) in the South American sloths genome (*Choloepus hoffmanni*), 2) Han and Worobey^{71a} described endogenous FVs (PSFVaye) in the Madagascan aye-aye, a primitive lemur species (*Daubentonia madagascarensis*), and more surprisingly, 3) in the latimera (*Coelacanth*) genome^{71b} (CoeEFV), suggesting that exogenous FVs existed more than 400 million years ago in species outside the mammals. Moreover, once an exogenous FV has adapted to its host, it mutates only slightly faster than the host mitochondrial DNA.²³⁴ The substitution rate of simian foamy viruses (SFVs) has been estimated to be around 1.7×10^{-8} per site and year.²³⁴ This makes FVs the most genetically stable of viruses, with an RNA phase in replication. For instance, the FV mutation rate is approximately ten times lower than primate T-cell lymphotropic virus type 1 (PTLV-1), a virus that replicates primarily by a proviral expansion mechanism (i.e., through DNA) (see Chapter 48).

FVs combine two favorable features: They are of extraordinary genetic stability and, if not acquired by *trans*-species transmissions, always point to the host species from which they were derived, and they are shed in feces. Owing to these features, NHP phylogeographic and conservation issues can be addressed easily without animal disturbance.^{135,220}

Curiously, the fidelity of the reverse transcriptase enzyme (RT) does not reflect this enormous genetic stability. If analyzed *in vitro*, the PFV RT was found to be of exceptional high

processivity but of low fidelity.^{23,24,197} The mutation rate of PFV RT (approximately 1.7×10^{-4} per site and replication round) is similar to that of human immunodeficiency virus (HIV).²⁴ Most mutations found were small deletions and insertions.²⁴ If analyzed in cell culture, such deletions and insertions were not found. However, a point mutation error rate of 1.1×10^{-5} per site and round of replication remained.⁶²

Thus, the genetic stability of FVs at the molecular level is not currently understood, and the involvement of as yet unidentified specific cellular factor(s) may play a role in this process.

REPLICATION *IN VITRO*

The host cell range for FVs is quite broad and includes species-independent primary cells or cell lines of fibroblastoid, epithelial, and lymphoblastoid origin, such as various B and T lymphocytes, and cells of erythroid and of myeloid lineages.^{94,154,159,186,268} Upon replication in adherent cell cultures, FVs induce massive multinucleated giant cell CPE (Fig. 52.1A), and apoptosis is thought to be the ultimate cause of cell death.¹⁵⁸ Vacuolization of cells is often only observed using primary isolates.

The paucity of cell lines resistant to FV infections has hindered the identification of the cellular receptor(s) required for entry by classical approaches. It is now appreciated that all FVs use the same cellular receptor, including those present on bird, reptile, and fish cells.^{12,89,230} Only two cell lines—Pac-2 zebrafish embryonic fibroblasts and the G1E-ER4 human erythroid precursors—have been reported to be refractory to infection.²³⁰ Thus, the means to screen complementary DNA (cDNA) libraries for FV receptor-related genes has now been established.

Whereas the characteristic CPE develops in adherent cells, this hallmark of FVs is often absent in cells of lymphoblastoid origin, in which FVs appear to become latent and intermittently reactivatable. Latently infected cells do not undergo syncytium formation and death but proliferate with normal kinetics and produce low amounts of virus.²⁶⁸ As judged from Southern blots, the viral DNA copy number oscillated in infected lymphocytes (unpublished observation). Interestingly, chemical treatment of lymphocytes (e.g., with phorbol esters) may induce the latent virus and cause cell death owing to activated viral replication.^{157,268} Although this is reminiscent of the lymphotropic herpesviruses, in FVs the molecular basis for virus reactivation has not been investigated nor have sites within the cellular or FV DNA genome responsive to the drug-mediated reactivation been mapped. Whether the methylation of FV DNA that has been observed in a cell culture model²¹⁹ contributes to *in vivo* latency remains unresolved, because there is no evidence of transcriptional down-regulation of FV vectors by methylation following their introduction *in vivo*.^{90,169,225}

REPLICATION IN THE NATURAL HOST *IN VIVO*

Recently, Liu et al.¹³⁵ used methods similar to those employed to demonstrate that human immunodeficiency virus type 1 (HIV-1) was derived from simian immunodeficiency virus from chimpanzees (SIVcpz; i.e., they collected and analyzed fecal samples from wild chimpanzees; see Chapters 49 and 50). They found that simian foamy virus from chimpanzees (SFVcpz) is widely distributed among wild chimpanzees with a

phylogeographic distribution and is transmitted horizontally, because babies younger than 2 years were free from FVs and infection rates increase with age. Moreover, they determined that superinfection by SFVs from lower primates and frequent recombination events occur. The most interesting finding by Liu et al has been the detection of viral RNA but not viral DNA in the fecal samples.¹³⁵ This finding directly relates to the FV replication pathway (see later discussion). However, Liu et al have not investigated whether the RNA-containing virus transmits the infection, and it is not known in which cell type these viruses were produced. It is possible that the DNA content in the fecal samples may have been too low to be detected even with very sensitive methods.

The tissue distribution of SFV and sites of *in vivo* replication have been investigated using another approach. As expected from the broad host cell range of FVs seen *in vitro*, viral DNA was detected at a frequency of one genome copy per 10^2 to 10^3 cells in every organ examined.⁵⁴ Because animals were perfused prior to the analysis of nucleic acids, infected lymphocytes were not detected, although these cells were the probable vehicles of virus dissemination *in vivo*.^{54,55} As judged from *in situ* hybridization experiments, viral RNA, indicative of active virus replication, was confined to superficial cells of the oral mucosa.^{54,165} Thus, it appears that only cells, which are destined to be shed, are productively infected and undergo lytic replication *in vivo*. Differential expression of yet undisclosed host factors restricting viral replication in other tissues is a likely explanation for this observation.

It is generally assumed that FVs are transmitted among NHPs through saliva via social contacts, including aggressive activities such as biting among young animals.^{31,135} These contacts and lactation are also suspected to be the main transmission route of the FFV,²⁵⁹ whereas BFV probably is mainly transmitted via milk from infected cows to offspring.¹⁹⁸

Early studies suggested that drug-induced immunosuppression of infected African green monkeys did not result in SFV-related symptoms yet enhanced the frequency of virus isolation (D. Neumann-Haefelin, Freiburg, Germany, personal communication). It was subsequently found that in dually SFV- and simian immunodeficiency virus (SIV)-infected and severely immunosuppressed macaques, the predominant site of FV replication changed from the oral mucosa to the small intestine.¹⁶⁴ However, SFV-related diseases did not occur. This was also observed in cats dually infected with feline immunodeficiency virus (FIV) and FFV.^{8,272} A case of human co-infections by HIV-1 and SFV from mandrills has also been reported, without clinical consequences that could be attributed to the SFV infection.²³³

ROLE OF ANTIVIRAL RESTRICTION FACTORS

APOBEC3

FV genomes are sensitive to editing by a variety of cellular catalytic polypeptide 3 apolipoprotein B messenger RNA (mRNA)-editing (APOBEC) proteins.^{41,141,205} To edit complementary DNA (cDNA) during reverse transcription, APOBEC3 proteins have to be encapsidated into the nascent virus particle. FVs encode the accessory Bet protein to preserve genome stability. The HIV-1 Vif protein prevents APOBEC3 particle incorporation by routing it to the proteasomal degradation pathway. In contrast, Bet prevents APOBEC3 encapsidation by binding and quantitatively trapping the deaminase.^{36,175} The PFV Bet

function was found to be broadly active against various primate APOBEC3 proteins.¹⁷⁵ However, some species specificity was also observed, as PFV Bet was found to be inactive against all or some mouse, feline, and rhesus monkey APOBEC3 proteins, as well as against human APOBEC3DE and APOBEC3H.¹⁷⁵ Because reverse transcription of FV RNA takes place to a significant degree in virus-producing cells (see later discussion), APOBEC3 restriction of FVs occurs at a different point in the replication cycle than that reported for orthoretroviruses.¹⁴¹

TRIM5 α

The tripartite interaction motif (TRIM) proteins comprise a large family of cellular proteins that are components of the innate immune defense mechanism and are active at various stages of replication against many viruses, including retroviruses.^{167,244}

TRIM5 α has been studied extensively for its activity against lentiviruses (see Chapters 8 and 49) and was found to be active against some orthoretroviruses during the very early phase of infection, prior to reverse transcription, by inducing premature disassembly of viral capsids. Lentiviral *gag* genes have evolved in such a way that their products are not neutralized by the homologous TRIM5 α but often by proteins from other species. TRIM5 α proteins have a modular organization consisting of so-called N-terminal RING domains, followed by zinc-binding B boxes, coiled-coil domains, and the C-terminal variable region B30.2/SPRY.^{167,244} The ability to recognize and bind in a species-specific manner to retroviral capsids is mediated by the B30.2 domain.²⁴⁴ FV *gag* genes are highly divergent from their orthoretroviral counterparts; thus, it was uncertain whether TRIM5 α would react against FVs and, if so, what the molecular basis would be. Nonetheless, it has been shown that primate TRIM5 α proteins restrict FVs in a species-specific manner.^{170,263} The specificity of TRIM5 α has been mapped to variable residues of the B30.2 domain, which are important for neutralization of lentiviruses, and to the N-terminal half of the FV Gag.²⁶³ The activity of TRIM5 α against divergent capsid proteins, including those of FVs, which do not mature into the canonical orthoretroviral matrix (MA), capsid (CA), and nucleocapsid (NC) subunits, implies an even wider structural recognition pattern than previously assumed.

Tetherin (CD317)

CD317/tetherin is an integral membrane protein with an N-terminal membrane-spanning domain and a C-terminal glycosyl-phosphatidylinositol anchor. CD317 interacts directly with the actin cytoskeleton and blocks the release of enveloped viruses from infected cells. In HIV-1-infected cells, it is antagonized by the accessory gene product Vpu, for HIV-2 by Env, and in some SIVs by the Nef protein (see Chapters 49 and 51). The fact that different lentiviruses developed effective strategies to neutralize CD317 argues for its *in vivo* importance. As is the case for other enveloped viruses, CD317 is also active against FVs.^{104,262} A FV protein antagonizing tetherin has not yet been identified. The activity of tetherin against PFV shows some mechanistic differences in comparison to HIV-1, because dimerization-deficient tetherin inhibits PFV replication with the same efficiency as the wild-type factor.²⁶²

Interferon

All three aforementioned restriction factors are inducible by interferon (IFN) to which FVs are vulnerable.^{56,150} Early studies indicated already that FVs are vulnerable to IFNs,^{194,195} and

it has been shown that toll-like receptor 7 (TLR7) expression in plasmacytoid dendritic cells is the likely factor in sensing FV RNA resulting in the induction of type I IFN.²⁰⁴ Replicating virus was found to be not required for this type of IFN induction. The addition of type II IFN abolishes FV replication *in vitro* almost completely, whereas the activity of type I IFN is less pronounced.^{56,150} The type I IFN-induced protein IFP35 has been demonstrated to down-regulate BFV transcription and replication by interacting with the *trans*-activator protein of BFV (Tas_{BFV}).²³⁶ Furthermore, the analysis of specific PFV *gag* arginine to lysine conversion mutants (see later discussion) revealed a likely antiviral role of IFNs that cannot be attributed solely to the three restriction factors discussed earlier.¹⁵⁰

Whether the IFN-inducible antiviral promyelocytic leukemia (PML) proteins play a role in restricting FV replication¹⁸³ needs further substantiation; PML proteins appear not to be involved in an establishing viral latency.¹⁵⁶

VIRION STRUCTURE AND VIRION NUCLEIC ACID

By ultrastructural analysis, FVs appear as immature-looking core particles surrounded by a lipid bilayer with embedded prominent Env proteins^{94,154,186,256} (Fig. 52.4). In negative-staining electron microscopy (EM), the virion has a diameter

FIGURE 52.4. A–C: Electron microscopy of negative-stained prototype foamy virus. The viral Env protein is arranged in trimers (arrowheads). (Adapted from Wilk T, de Haas F, Wagner A, et al. The intact retroviral Env glycoprotein of human foamy virus is a trimer. *J Virol* 2000;74:2885–2887.) **D:** Scheme of the complete viral particle prior to reverse transcription. Glycoprotein complex: leader peptide (gp18LP), surface (gp80SU), and transmembrane (gp48TM) subunits. Capsid: Gag precursor (pr71Gag), large processing product (p68Gag). Viral enzymes: protease-reverse-transcriptase (p85PR-RT), integrase (p40IN). (Modified from Lindemann D, Rethwilm A. Foamy virus biology and its application for vector development. *Viruses* 2011;3:561–585.)

of approximately 110 nm and a core of approximately 60 nm.^{94,154,186,256} The core has an immature morphology owing to the very limited cleavage of the Gag precursor protein by the viral protease (PR) (see later discussion). The cores of infectious PFV virions are made up of the Gag precursor pr71^{Gag} and its larger processing product p68^{Gag} at a ratio of 1:1 up to 1:4.³³ This Gag doublet is seen with all FVs,⁷¹ although the nonprimate FV capsid proteins are considerably smaller than their primate relatives.^{92,119,199,242} The core is probably oriented radially with the Gag N-terminus pointing outward in the direction of the Env proteins²⁵⁶ (Fig. 52.4C). The prominent surface spikes average 15 nm in length and are organized as trimers in ring-like structures.²⁵⁶ A feature that PFV shares with HBV is the formation of subviral particles (SVPs) consisting only of membranous Env-containing vesicles and devoid of cores.^{224,228}

It appears that FV particles contain fewer Pol molecules than orthoretroviruses, which is consistent with the high processivity activity of its RT.^{23,197} The interpretation of older studies demonstrating equal amounts of Pol in foamy and orthoretroviruses³³ have been complicated by the detection of significant amounts of extraparticular Pol protein present in FV particle preparations of different origin as reported by Swiersy et al.²³¹ This study also revealed that in sharp contrast to orthoretroviruses, FV replication tolerates a great imbalance in the relative ratios of Gag and Pol molecules in virus producing cells.²³¹ This is owing to the unusual Pol encapsidation strategy of FVs (see later discussion), in which viral RNA is the limiting factor at conditions of high cellular levels of Pol.

The physical stability of FVs has not been directly compared with that of orthoretroviruses. However, owing to their immature core and a particular Env topology (see later discussion), FVs are probably quite stable. This is illustrated by the fact that vector particles can be concentrated more than 100-fold (i.e., by ultracentrifugation) without great loss of infectivity.^{65,89}

Viral nucleic acid is present within the core of extracellular FV particles, and it appears to be a mixture of RNA

and DNA. RNA dominates at a ratio of approximately 1:1 to 7:1, depending on the genomic region analyzed (long terminal repeat [LTR] vs. *gag*).^{203,269,270} Consistent with this, both forms of nucleic acid were detected in plasma and saliva of an experimentally infected cynomolgus macaque by PCR and RT-PCR.²⁵ Full-length DNA was shown to be present in roughly 5% to 20% of FV virions, and functional studies using the RT-inhibiting drug AZT indicated DNA to be the relevant genome for infection, at least at the high multiplicity of infection (MOI) studied.^{150,160} Because DNA was found in PFV and FFV virions, the idea that FVs are facultative DNA viruses may be generalized.²⁰³

However, it has not been investigated in much detail to what extent reverse transcription is taking place late in the replication cycle. For instance, it is likely that there are genomic regions, such as the gap in the plus strand cDNA (see later discussion), that still remain single stranded. The finding of more LTR than *gag* region reverse transcripts in virions is a clear indication of this.^{203,269} In addition, because more RNA than DNA is found in virions, it would be interesting to know whether purely RNA-containing viruses exist or whether most viruses contain both forms of nucleic acids.

It is with respect to reverse transcription taking place at a late step in viral replication that FVs diverge at most from orthoretroviruses, which display a RNA to DNA ratio of approximately 10⁵:1 in extracellular virions.²⁰³ The most compelling evidence for this are experiments in which the infectivity of virion-extracted FV DNA has been demonstrated.^{150,203,269} Thus, FVs functionally bridge the replication pathways of orthoretroviruses and hepadnaviruses (Fig. 52.5). It is because of this analogy to the hepadnaviral replication cycle (see Chapter 68) that the full-length FV RNA has been termed (*pre*-) *genomic*.

In addition to reverse transcription in late phases of FV particle morphogenesis, it has been shown that, similar to orthoretroviruses, reverse transcription also occurs during the early phases of FV replication upon target cell entry.^{42,270} Given

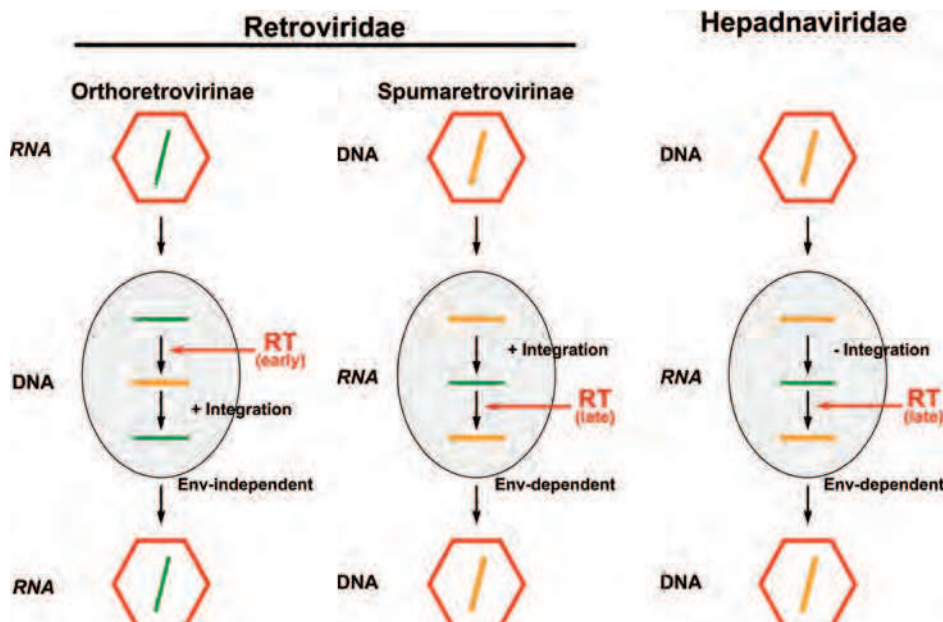

FIGURE 52.5. Principal replication strategies of reverse transcribing viruses. Whereas orthoretroviruses (**left panel**) are RNA viruses that reverse transcribe early in replication, replicate through a DNA intermediate, and exhibit obligate integration into the cellular genome, hepadnaviruses (**right panel**) essentially are DNA viruses replicating through an RNA intermediate; they must not integrate. The retroviral subfamily of spumaretroviruses (**middle panel**) functionally bridges both pathways by being DNA viruses, reverse transcribing late in replication (like hepadnaviruses), and requiring proviral integration (like orthoretroviruses).

the aforementioned ratios of RNA to DNA in extracellular viruses, reverse transcription during the early phase of FV replication may only become relevant at a very low MOI, when the amount of virion DNA may be too low to sustain a productive infection.²⁷⁰ Furthermore, the discrepant results reported about the importance of the differentially timed reverse transcription events for FV infectivity may reflect the inherent differences in the cell types used for virus production.^{42,150,160,203,269,270} In essence, the generally accepted view that virions contain either an RNA or DNA genome, but not both, may not apply to FVs.

GENOME ORGANIZATION

The schematic representation of the genome of PFV is shown in Figure 52.6. All FV genomes share common genome structures.¹⁹¹ Between the LTRs, the canonical *gag*, *pol*, and *env* genes are found; downstream of *env*, the accessory open reading frames (ORFs) are found. Proviruses are 12 to 13 kb—long

in comparison to those of other retroviruses. The large size of FVs genomes is partially attributed to the extraordinary long U3 regions of the LTR, which can be explained in part by the overlapping ORF-2 (see Fig. 52.6). However, the accessory ORF-2 reaches only to some extent (approximately 300 bp, in the case of PFV) into the more than 1.4 kb long U3 region, leaving several hundred bases without known function. In the latter, very few enhancer elements, such as those for AP-1 and Ets-1,^{152,213} and the short sequence motifs responsive to the viral transactivator (see later discussion), are present.

There are length differences in the *gag* genes in different FVs, with those in FVs from cats, bovines, and equines being shorter than those from primates.^{92,151,242,258} In sharp contrast to their orthoretroviral cousins, the FV Gag proteins are more variable in their sequence than are the Env proteins.^{186,238} For instance, primate lentiviruses have an amino acid conservation of roughly 60% in Gag and 40% in Env compared to 45% in Gag and 65% in Env among primate FVs.^{186,238} It is likely that this curiosity of FV biology is a consequence of the

FIGURE 52.6. Prototypic foamy virus genomic structure, gene regulation, and messenger RNA (mRNA) transcripts originating at the two promoters. LTR, long terminal repeat; *gag*, *pol*, *env*, genes for virion-associated proteins; *tas* and *orf-2*, regulatory genes; IP, internal promoter giving rise to the accessory Tas and Bet proteins. If sufficient amounts of Tas have been made, the transcriptional activator switches on gene expression from the U3 promoter in the LTR. The (pre-) genomic transcript contains the primer binding site (PBS), central and 3' polypurine tracts (cPPT and 3' PPT, respectively), a motif required for activating the protease (PARM), and *cis*-acting sequences (CAS) I through III essential for packaging the RNA (pre-) genome, the Pol protein, reverse transcription, and integration. ΔTas, resulting from reverse transcription of the depicted nearly full-length (pre-) genomic RNA from which the *tas* intron has been spliced out, is replication defective (see text for details). ΔTas may generate some Bet protein. PR, protease; RT/RH, reverse transcriptase - RNase H; IN, integrase; LP, leader peptide; SU, surface; TM, transmembrane - subunits. ©, mRNA cap site; A_n, poly A tail. (Modified from Lindemann D, Rethwilm A. Foamy virus biology and its application for vector development. *Viruses* 2011;3:561–585.)

process of adaptation to and co-evolution with their natural hosts. Furthermore, this finding is consistent with the use of the same cellular receptor(s) by all FVs.

All FV genomes encode an internal promoter (IP) near the 3' end of their *env* genes, which drives the expression of the accessory ORFs^{137,140} (see Fig. 52.6). The primer binding site (PBS) is complementary to the cellular transfer RNA_{lys1,2} and is conserved among all FVs.¹⁵¹ Another feature of all sequenced FV genomes is the presence of a central polypurine tract (cPPT) in addition to the polypurine tract (PPT) upstream of the 3' LTR^{118,176,221,243} (see Fig. 52.6). The cPPT is believed to enhance reverse transcription.^{176,243} In contrast to HIV-1, it does not lead to a DNA *flap* region but to a single-stranded DNA *gap* without defined ends and start points of the upstream and downstream respective DNA plus strands.¹⁷⁶

VIRION-ASSOCIATED PROTEINS

Gag

The FV capsid proteins have several unusual characteristics compared to orthoretroviral Gag proteins. They are probably translated by ribosomal shunting from the (pre-) genomic RNA²¹¹ (see Fig. 52.6). This is a mechanism that is used by plant pararetroviruses to translate their *gag* homolog^{91,207} and involves the selective jumping of ribosomes to the translation initiation site.⁶¹ Even more surprisingly, FV Gag proteins are neither cleaved into the canonical MA, CA, and NC subunits, nor are several sequence motifs present, which are conserved in all orthoretroviral Gag proteins (Fig. 52.7). These include the N-terminal myristoylation signal of the MA domain, the major homology region (MHR) in the CA domain, or the cysteine-histidine (CH) boxes in the NC domain. Instead of Gag subunit processing observed with orthoretroviruses, at least half of the particle-associated FV Gag molecules are truncated approximately 3 to 4 kD C-terminally by *pol*-encoded PR processing at a singular cleavage site. In the case of PFV, this generates a large PFV p68^{Gag} and a small PFV p3^{Gag} product from the PFV pr71^{Gag} precursor molecule⁶⁰ (see Fig. 52.7). Whereas the p68^{Gag} cleavage product together with the pr71^{Gag} precursor forms the capsid of secreted PFV virions, the smaller p3^{Gag} is not thought to be particle associated and its cellular localization and fate are unclear.^{48,193a} FV Gag cleavage is required for infectivity, as FVs expressing only the pr71^{Gag} precursor are not infectious and often produce aberrantly formed capsids.^{48,114,271}

Mutants expressing only the large p68^{Gag} cleavage product are infectious albeit at low titers.^{48,229,271} Secondary protease cleavage sites, located in the central part of FV Gag, have been identified *in vitro*, using recombinant proteins and peptides¹⁷⁹ (see Fig. 52.7). They are believed to be essential and utilized for a viral disassembly process involving proteolytic processing of Gag by the FV PR and cellular proteases following entry into target cells.^{66,75,125,179} Thus, FV capsid disassembly appears to be a unique process controlled by viral and cellular proteases.

One of the most distinctive features of FVs is the failure of their capsids to spontaneously bud from cellular membranes and generate virus-like particles (VLPs). This is owing to the absence of a membrane-targeting signal in Gag.^{7,58,181} For cellular egress, FVs require the cognate envelope protein, with which FV capsids specifically interact. Co-expression of FV Gag and FV Env is required for detection of capsids secreted into the cell culture supernatant (Fig. 52.8). However, whether a direct capsid–Env interaction or an indirect cellular protein-mediated interaction exists has not been established by biochemical means. Biophysical investigations (applying surface plasmon resonance to recombinant protein fragments) with FFV and morphologic studies (with cryo-EM) of PFV^{64,257} suggest that a direct interaction between Gag and Env occurs. As a consequence of this unique feature, pseudotyping of wild-type FV capsids by anything other than FV glycoproteins cannot take place.¹⁸¹ Capsids exhibit a marked preference for virus type-specific Envs when FVs from different species are examined (unpublished own observations).

Various peptide and structural motifs have been found in FV Gag proteins, and these have been partially functionally characterized (see Fig. 52.7). Four coiled-coil domains (CC1–4) are predicted to be present in the PFV Gag, and functions have been assigned to the first three. The CC1 (aa 4–19) at the N-terminus has been suggested to interact with domain for the Env leader peptide (LP),^{129,193a} although unequivocal biochemical evidence has yet to be provided. CC2 (aa 133–146) has been reported to harbor a domain required for Gag multimerization,²⁴⁰ and CC3 (aa 161–174) is believed to be required for the incoming capsids to interact with the dynein light chain 8 for retrograde movement along the cellular microtubule network to the microtubule organizing center (MTOC).¹⁷⁸ The function of CC4 (aa 436–453) remains unknown.

Similar to Mason-Pfizer monkey virus (MPMV), a cytoplasmic targeting and retention signal (CTRS) is located at the N-terminus (aa 43–60) of PFV Gag^{32,46} (see Fig. 52.7).

FIGURE 52.7. Primary structure of the 71-kD prototype foamy virus Gag protein. The Gag primary (solid arrows) and secondary (dashed arrows) cleavage sites by the viral PR, the four coiled-coil (CC) domains, the three glycine-arginine boxes (GR), the cytoplasmic targeting and retention signal (CTRS), the PSAP late budding motif (L), and the YXXLGL motif (A) required for correct particle assembly are indicated (see text for details). (Modified from Lindemann D, Rethwilm A. Foamy virus biology and its application for vector development. *Viruses* 2011;3:561–585.)

FIGURE 52.8. A: Autologous Env is required for FV particle (Gag) egress. Foamy virus proteins of 293T cells transfected with vector only (lanes 1 and 4), a *gag/pol* gene expression plasmid (lanes 2 and 5), or in addition with an *env* gene expression plasmid (lanes 3 and 6). Cellular lysates (cells) and particulate material from the supernatants (virus) were partially purified by ultracentrifugation and were reacted with a Gag antiserum. (Modified from Fischer N, Heinkelein M, Lindemann D, et al. Foamy virus particle formation. *J Virol* 1998;72:1610–1615, with permission.) **B:** Gag is required for surface expression of Env. As soon as env-expressing cells are co-transfected with an expression vector for the autologous *gag* gene, massive syncytium formation develop, which is indicative for the surface expression of Env. (Modified from Pietschmann T, Zentgraf H, Rethwilm A, et al. An evolutionarily conserved positively charged amino acid in the putative membrane-spanning domain of the foamy virus envelope protein controls fusion activity. *J Virol* 2000;74:4474–4482.)

However, unlike MPMV, mutation of a conserved arginine in the CTRS did not lead to a switch from a B/D to a C-type capsid assembly strategy. Instead, mutation of the analogous arginine in PFV Gag completely abolished particle release.^{46,129} Release of FV CTRS Gag mutants was rescued by the addition of a N-terminal, heterologous myristoylation signal that also permitted capsid release in the absence of Env.^{46,129,136,274} However, these altered particles were non-infectious even in the presence of the authentic Env.^{46,129} This result suggests that the CTRS of MPMV and FV Gag are functionally different.

A late assembly (L) domain, specified by the motif PSAP (AA 284–287 of PFV Gag), interacts with the cellular export machinery (vacuolar protein sorting [VPS]) via TSG101 to mediate release of virus particles from the plasma membrane^{174,227} (see Fig. 52.7). However, PSAP motifs are absent in nonprimate FV Gag proteins, and their functional L-domains remain to be identified.²²⁷ Interestingly, ubiquitination of PFV Gag—a common feature of orthoretroviral capsids upon interaction with the VPS machinery—has not been observed.^{228,276} This suggests that ubiquitin conjugation to transacting cellular factors, not the Gag protein itself, may be critical for ubiquitin-dependent particle release of enveloped viruses.^{273,274}

Three domains, rich in glycines and arginines (GR-boxes), have been identified at the C-terminal regions of PFV Gag²¹²

(see Fig. 52.7). GR-box I (AA 485–495) is believed to have nucleic acid-binding properties.²⁶⁶ PFV GR-box II (AA 547–557) was initially reported to contain a basic nuclear localization signal (NLS) in its C-terminal half,²¹² whereas the N-terminus contains a chromatin-binding site (CBS) that tethers incoming PFV to the chromatin of the host cell by interacting with H2 core histones.²⁴¹ Nuclear localization of the Gag protein is a common feature of most FVs and leads to the strong nuclear fluorescence detected in IFA using homologous serum (see Fig. 52.1B). It has been recently reported¹⁶¹ that nuclear localization of PFV Gag might be an epi-phenomenon reflecting the tethering of Gag to chromatin via its CBS during mitosis. No specific function has been assigned to GR-box III (AA 601–611). Another study has reported that the GR-boxes are important for RNA encapsidation, (pre-) genome reverse transcription, particle morphology, and virion infectivity.¹⁶² In addition, GR-box III has been reported to functionally substitute for GR-box I, indicating some functional redundancy.¹⁶² Other sequences in PFV Gag, such as a conserved YXXLGL motif (AA 464–467), have also been shown to participate in particle assembly and reverse transcription¹⁴⁹ (see Fig. 52.7).

An unusual and distinguishing feature of FV Gag proteins is their paucity of lysine residues.^{150,228,274} PFV Gag contains only a single lysine residue that is required for replication in primary cells.¹⁵⁰ In contrast, there are 64 arginine residues in

PFV Gag. The probability that this uneven distribution occurs randomly is very low (1.8×10^{-18}).¹⁵⁰ Curiously, viral replication in continuous cell lines was not altered if some of the arginine-specifying residues were changed to lysine-specifying codons. In contrast, several of these mutants replicated poorly in primary cells in the presence of type I IFN.¹⁵⁰

In summary, FV capsids share various features with the core of hepadnaviruses (i.e., glycoprotein dependence for budding, nuclear localization, and the presence of arginine-rich motifs) as well as with orthoretroviruses (i.e., presence of an L-domain and a CTRS). There are also Gag characteristics that are unique to FVs, particularly their unusual cleavage pattern. Furthermore, alterations of conserved FV Gag motifs result in morphologic defects that affect the ability of capsids to support intraparticle reverse transcription and render such mutants noninfectious.

Pol

Pol is translated separately from Gag from its own spliced mRNA, using the major splice donor in the R region of the LTR and a suboptimal splice acceptor in the PFV gag ORF, which prevents *pol* mRNA from becoming too abundant^{20,49,103,122,138,264} (see Fig. 52.6). On the other hand, FV mutants have been reported to be replication competent when *pol* was expressed in-frame with the preceding *gag* ORF or by an orthoretroviral-like frameshift mechanism.²³¹ From orthoretroviruses, it is known that expression of a Gag-Pol fusion protein alone is incompatible with viral replication owing to severe particle assembly or release defects.^{11,57,107,171,254} Furthermore, these defects often involved the orthoretroviral PR that was either found to be in- or hyperactive. The finding of FV replication tolerating expression of an in-frame Gag-Pol fusion protein indicates a mode of Pol encapsidation and regulation of PR domain activity that is unique to these viruses and different from that observed for orthoretroviruses (see later discussion). In the BFV system, equal amounts of *gag* and *pol* mRNAs have been reported.⁹² Whether this also leads to similar amounts of intracellular Gag and Pol proteins has not been investigated.

Historically, the discovery of a spliced *pol* mRNA and large amounts of virion DNA represent a landmark in retrovirus research.²⁶⁴ PFV Pol is translated as a large, approximately 127-kD polyprotein harboring enzymatic domains of PR, RT, RNase H (RH), and IN from N- to C-terminus (Fig. 52.9). Unlike orthoretroviruses, the PFV pr127^{Pol} precursor is processed by the viral PR following particle release into only two mature subunits: p85^{PR-RT} and p40^{IN}.⁶⁰ FV PR does not exist as a separate subunit. Both Pol subunits have been reported to localize to the nucleus in infected cells.⁹⁸ FV Pol precursor

processing is required for virus replication.^{114,202} For the PFV IN subunit, NLS sequence motifs have been characterized.^{6,97}

All retroviral PRs (including the FV PR) are active as dimers. So the question arises, how is FV Pol dimerization accomplished? In orthoretroviruses, this is facilitated by Gag oligomerization of the Gag-Pol fusion protein; however, this is not possible for FVs. Biochemical and biophysical evidence point to transient dimer formation of the FV Pol, as the enzyme is purified always as a monomer, except under the nonphysiologic conditions of high salt.⁷⁶ A role of RNA in PR activation was proposed by Hartl et al.⁷⁵ by identifying a *pol* ORF-located RNA protease-activating RNA motif (PARM) present on (pre-) genomic RNA. By binding to PARM, the p85^{PR-RT} PFV Pol subunit dimerizes and PR is activated. Although the entire process has not yet been elucidated, this mechanism would explain the replication competence of viral mutants expressing an in-frame Gag-Pol protein, because they also would rely on activation of PR by PARM, which would be the rate-limiting step.

Another important question deals with the mechanism of Pol protein encapsidation, because the encapsidation of Pol via protein-protein interaction of the fused Gag precursor, as it occurs with orthoretroviruses, cannot apply to FVs. Two competing views on this exist for the initial step of Pol incorporation: one favoring Gag-Pol protein-protein interactions (when proviral mutants were analyzed) and the other Gag and Pol protein-RNA interactions with viral (pre-) genomic RNA serving as a bridging molecule (when subgenomic vectors were analyzed).^{79,123,177} Probably both mechanisms are involved in encapsidating Pol; however, a definitive answer to this question remains open.

The FV RTs bear in the active center the motif YXDD and are sensitive to nucleoside analog RT inhibitors, such as AZT.^{115,121,197,200}

The solution structure of the PFV RNase H domain has been determined by Leo et al.¹²⁷ RNase H is an endonuclease covalently coupled to the RT domain of Pol, and it hydrolyzes the RNA template strand in RNA/DNA hybrids during reverse transcription. This activity is essential for virus replication.^{185,239} Like the murine leukemia virus (MLV) enzyme but unlike HIV RT, FV RNase H possesses a protruding basic loop and the so-called C-helix.²³ This structure has recently been validated for the PFV RNase H by nuclear magnetic resonance (NMR) spectroscopy,¹²⁷ and information on the function of the basic protrusion remains to be determined.

FV replication depends on integration mediated by the active IN.^{50,153} A 4-bp duplication of staggered chromosomal nucleotides occurs at the site of integration.^{50,153} Orthoretroviruses utilize 3'-end processing as the initial step of the integration

FIGURE 52.9. Primary structure of the 127-kD prototype foamy virus Pol protein. The PR domain is not separated from the RT/RH domain. The only viral PR-mediated cleavage event separates the p40^{IN} subunit from the rest of the protein. Conserved domains within the active center of RT (YVDD)^{160,197} and of IN, with the N-terminal domain (NTD) that is Zn²⁺-binding, the catalytic core domain that harbors the DD35E motif, and the C-terminal (CyD) DNA-binding domain are indicated. (Modified from Lindemann D, Rethwilm A. Foamy virus biology and its application for vector development. *Viruses* 2011;3:561–585.)

FIGURE 52.10. The architecture of the prototype foamy virus intasome. The crystal structure (PDB ID 3OY9) is shown as viewed along (**bottom panel**) or perpendicular (**top panel**) to its twofold axis. Viral DNA (vDNA) chains are shown as cartoons and colored by chain; vDNA bases and active site IN residues are shown as *sticks*. Gray spheres are metal cations. Locations of IN domains (NTD, CyD, and CCD) are indicated. (Courtesy of P. Cherepanov, London, UK.)

reaction. This involves the removal of two nucleotides from each terminus of the blunt-ended linear viral DNA. During FV integration, only the 3' terminus (within the U5 region) of the viral DNA undergoes processing, whereas the 5' end (the U3 region of the LTR) remains unprocessed, possibly because it is already suitable for integration.^{50,105}

In 2010, a seminal study was published that described the crystal structure of full-length PFV IN bound to its cognate DNA, as tight complex, termed the *intasome*⁷² (Fig. 52.10). This achievement was possible because, unlike the orthoretrovirus IN protein, the recombinant PFV IN is uniquely soluble and active *in vitro*.²⁴⁸ These properties contrast with the aggregation and poor enzymatic activity observed with other retroviral INs, regardless of the expression system used.

Classically, retroviral INs are subdivided into three domains (see Fig. 52.9): (a) an N-terminal Zn²⁺ binding domain (NTD), characterized by pairs of His and Cys residues (HHCC motif); (b) a catalytic core domain (CCD), harboring the Asp, Asp-35-Glu (DD35E) motif; and (c) a nucleic acid-binding Arg/Lys-rich C-terminal domain (CyD).²⁷ These

domains are connected by nonconserved flexible linkers. Early studies reported nonspecific DNA-binding activity by the CyD, and it was assumed that retroviral INs would adopt a dimeric or tetrameric structure when engaged with the viral DNA ends.²⁷ It was also hypothesized that multimers were highly flexible,²⁵³ and several contrasting structures of the retroviral intasome had been proposed. Crystallization of the PFV intasome has revealed the definitive answer to a long-standing puzzle. The viral integration apparatus contains a tetramer of IN, assembled on a pair of viral DNA ends, in which all three IN domains and interdomain linkers are involved in intimate protein–protein and protein–DNA interactions cross-linking the complex in a rigid structure.⁷² Further co-crystallization of the PFV intasome with target DNA (a mimic of the host cell DNA) revealed the assembly of the entire retroviral synaptic integration complex prior to and following strand transfer.¹⁴⁶ Moreover, because of the structural and functional similarity of PFV and HIV-1 INs, the mechanism of action of clinically useful HIV IN strand transfer inhibitors (raltegravir, elvitegravir, and dolutegravir) was elucidated.^{73,74,116} Using the PFV

FIGURE 52.11. (Modified from Lindemann D, Rethwilm A. Foamy virus biology and its application for vector development. *Viruses* 2011;3:561–585.)

intasome as a surrogate for its HIV counterpart, it was shown that these small molecule inhibitors bind to the active site of IN and displace the reactive 3'-hydroxyl group of the viral DNA, thereby preventing strand transfer.³⁷ The availability of the PFV intasome co-crystal structures with target DNA may facilitate the development of “designer integrases” possessing site-specific integration properties.¹⁴⁶

Env

The Env glycoprotein of FVs has an unusual primary structure and topology (Fig. 52.11A). PFV Env is synthesized as a large precursor protein of 988 aa (gp130–140^{Env}). It is tripartite, consisting of gp18^{LP}, gp80/85^{SU} surface (SU), and gp48TM transmembrane (TM) subunits.¹³⁰ The Env precursor is not co-translationally processed by the cellular signal peptidase complex, which naturally removes N-terminal signal peptides required for targeting glycoproteins to the secretory pathway. Therefore, unlike orthoretroviruses, which have their glycoprotein membrane anchored only in the TM domain, the FV Env spans the cellular membrane twice with the N- and C-terminal regions of the precursor located in the cytoplasm¹³⁰ (see Fig. 52.11B). The peptide backbone of the PFV Env precursor protein is cleaved between LP and SU (after aa 126) and between SU and TM (after aa 571), during cell surface transport in the late Golgi complex, by furin-like cellular proteases.^{45,63} The SU-TM cleavage is required for infectivity, whereas the LP-SU cleavage is not.⁴⁵

As a consequence, the mature gp18^{LP} subunit is an integral component of the virion and transverse the viral membrane at the N-terminus (a type II *trans*-membrane protein), as does the TM subunit at the C-terminus of Env (a type I *trans*-membrane protein)^{130,257} (see Fig. 52.11B,C). All three Env subunits are heavily glycosylated. Fourteen N-linked glycosylation sites

have been mapped, only two of which (N8 and N13 located in PFV SU and PFV TM, respectively) are essential for viral infectivity¹⁴⁵ (see Fig. 52.11A).

The C-terminal cytoplasmic tail domain (CyD) of the TM subunit is rather short (comprising 16 aa), and its presence is not required for particle egress.¹⁸¹ In contrast, the N-terminal CyD of the LP subunit, comprising approximately 68 aa, is considerably longer. Alteration of conserved tryptophan residues in the LP N-terminal CyD (at aa positions 10 and 13 of the PFV LP) abolished interaction with the Gag protein.^{130,257} Not only is FV Env required for export of capsids (see Fig. 52.8A), but *gag* gene expression is also necessary for the transport of Env to the cell surface. This implies that highly specific direct or indirect interactions influence the intracellular distribution and trafficking of both proteins^{32,58,181} (see Fig. 52.8B).

Aside from its interaction with Gag, two additional factors appear to regulate Env intracellular trafficking and transport to the cell surface. First, a dilysine motif, known to be responsible for retrieval of glycoproteins to the endoplasmic reticulum (ER), is present near the C-terminus of the TM⁶⁹ (see Fig. 52.11A). Although this signal can sort Env to the ER, it is not required for efficient virus replication⁷⁰ and, in comparison to the other factors, has only a weak effect on Env intracellular distribution. Second, posttranslational ubiquitination of four of five lysine residues located within the LP subunit N-terminal CyD also appears to mediate efficient Env removal from the cell surface^{226,228} (see Fig. 52.11B,C).

The PFV Env has been shown to support not only viral particle release from cells but also release of SVP from other cellular membranes harboring the viral glycoprotein.²²⁴ This is again analogous to a similar process observed with hepadnaviruses, which secrete vast amounts of SVPs, the so-called Australia antigen (see Chapter 68). Ubiquitination appears to

suppress the intrinsic activity of the FV glycoprotein to induce SVP release, and mutants of the lysine-specifying codons in the LP CyD release large amounts of SVP.²²⁸ These PFV Env mutants appear to be particularly well suited to pseudotype orthoretroviral capsids, in contrast to the wild-type PFV Env, probably owing to its low level of cell surface expression (own unpublished observation).

Surprisingly, the gp130–140^{Env} is not the only FV glycoprotein synthesized. Using conserved splice sites within *env* ORF of the FV genome (see Fig. 52.6), alternatively spliced *env* transcripts are generated that are translated into fusion proteins consisting of Env lacking the membrane-spanning domain of TM in-frame with the Bet protein (Env-Bet)^{67,131} or, as in the case of FFV, with the ORF-2 encoded peptide sequence (Env-Bel2).¹⁹ The Env-Bet fusion protein is secreted into the supernatant of PFV-infected cells and processed into LP, SU, and ΔTM-Bet subunits that are not viral particle associated.¹³¹ This fusion protein is synthesized at 50% of the level of particle-associated gp130–140^{Env}, suggesting that it may have a useful function.¹³¹ However, replication-competent PFV mutants deficient in Env-Bet synthesis do not exhibit a distinctive phenotype, and no revertants with restored Env-Bet expression have been observed in cell culture, although this fusion protein could be functionally important *in vivo*.¹³¹

In summary, the biosynthesis and membrane topology of the FV Env are highly unusual. The Env LP subunit is an integral component of the particle-associated Env complex and harbors in its CyD the major interaction domain with FV capsid essential for viral particle budding. The interaction of Env with Gag and ubiquitination of the CyD of the Env LP subunit seem to be the main determinants of its intracellular transport and are probably dominant over the C-terminal dilysine motif. Furthermore, some properties of orthoretroviral Gag proteins, such as ubiquitination and budding functions, have been delegated to Env in FVs. In addition, the function of the unusual Env-Bet/Bel 2 fusion proteins is unknown.

FIGURE 52.12. Prototype foamy virus Tas protein with functional domains, the region shared with Bet that harbors a multimerization domain (SR/MD), the centrally located DNA-binding domain (DBD) that is followed by the region specifying the nuclear localization signal (NLS), and the C-terminal activation domain (AD).

NONSTRUCTURAL PROTEINS

Tas

Tas is the *trans*-activator of spumaviruses and is required for replication.^{142,193} PFV Tas (Tas_{PFV}) is a 35-kD nuclear protein that binds to upstream DNA elements in, and augments gene expression from, both the IP and the U3 LTR promoter^{34,109,137,139} (see Fig. 52.6). Most Tas protein is translated from a spliced mRNA initiated at the IP.^{10,19,137,163} Tas is variable in size (209 aa in FFV and 300 aa in PFV) and has a modular organization (Fig. 52.12).^{77,137,189} Its N-terminus contains a region of variable length that is shared with the Bet protein, the other accessory FV protein, and harbors a multimerization domain. Unique to Tas are a central DNA-binding domain (DBD) of approximately 100 aa, a basic NLS, and a C-terminally located acidic activation domain (AD) of around 30 aa.

Except for the AD, Tas shows no homology to known cellular proteins,¹³⁷ and there is little or no cross-*trans*-activation between different FVs.¹³⁷ The reason for this is the species specificity of the Tas DBD, which is highly variable in aa sequence among different FV Tas proteins. This is consistent with the highly divergent DNA targets that mediate Tas function among different FVs (Table 52.2). This is in contrast to the acidic Tas

TABLE 52.2 Tas Binding Sites in Different Foamy Virus Internal Promoter and U3 Promoter Elements Reveal Little Consensus

IP, internal promoter; TBS, Tas binding site; PFV, prototype foamy virus; SFVmac, simian foamy virus in the macaque; FFV, feline foamy virus; BFV, bovine foamy virus.

FIGURE 52.13. Prototype foamy virus Bet protein with the SR/MD. The domain probably involved in antagonizing APOBEC3 enzymes (AAD) is located C-terminal from the SR/MD.

AD, which shares conserved amino acids with other viral and cellular transcriptional activators and is also active in yeast.¹⁴ For transcriptional activation, the Tas protein has to multimerize—a process that is apparently facilitated by residues located within the N-terminal domain shared with the Bet protein (SR/MD). This property has been demonstrated experimentally for Tas_{BFV} and can probably be generalized to all FV Tas proteins.²³⁷

Little is known about likely cellular factors that might interact with Tas.¹¹³ Phosphorylation by DNA-PK is required for full Tas activity, and only acetylated Tas protein has full DNA-binding capacity.^{15a,18,35} In addition, the ADA2 adaptor molecule is required for Tas AD-mediated activation in yeast.¹⁴

Research carried out on cellular factors engaged with Tas_{BFV} has led to the identification of RelB, which interacts with Tas_{BFV} and activates the nuclear factor κB (NF-κB) pathway.²⁵² However, whether these results also apply to Tas proteins other than Tas_{BFV} is not known. Furthermore, the NF-κB-mediated transcriptional enhancement seen is unlikely to explain the full activity of Tas.

Tas can activate cellular genes if they—probably by chance—harbor Tas-responsive DNA elements.^{137,251} This has been investigated for various human genes activated by Tas_{PFV}.^{137,251}

Bet

Bet is the least conserved of all FV proteins (Fig. 52.13). It is translated predominantly from multiply spliced mRNAs originating at the IP and to a minor extent from mRNA variants initiating at the LTR promoter^{10,163} (see Fig. 52.6). The *tas* ORF-located splice sites utilized for generation of the *bet* mRNA are highly efficient, resulting in Bet to be always made in vast excess over Tas. Because the shared region at the N-terminus appears to harbor the multimerization domain of Tas, it is likely that Bet also multimerizes via this domain. Aside from antibodies against the Gag protein that are diagnostic, infected individuals sometimes develop antibodies against this highly expressed protein, which are of some help in confirming the serodiagnosis.⁷¹

For a long time, no clear function could be attributed to Bet. For PFV, it was shown to be dispensable for *in vitro* replication in most cell types, with only a minor decrease in viral titer.^{10,267} The first generation of FV vectors actually had the ORF-2 region encoding for most of Bet replaced by sequences of interest so that they were under Tas-dependent transcriptional control of the IP or of an inserted heterologous promoter.²¹⁵ For FFV, a more drastic reduction in viral titers was observed for Bet-deficient viruses when grown on feline CRFK cells but not on human 293T cells.³ This observation eventually led to the identification of Bet being an antagonist of APOBEC3, similar to HIV Vif.¹⁴¹ However, unlike Vif, PFV Bet does not induce degradation of APOBEC3³⁶ but instead inhibits its dimerization by directly binding to the dimerization domain.¹⁷⁵ The regions of Bet involved in this physical interaction are under

investigation. Studies with FFV Bet suggest that these regions are located outside of those shared with Tas (M. Löchelt, Heidelberg, personal communication).

The splice sites that lead to generation of the Bet protein appear to be so efficient that they are used also in (pre-) genomic RNA. An integrated FV has been described that carries the characteristic deletion leading to the generation of Bet (ΔTas)²⁰⁹ (see Fig. 52.6). As the (pre-) genomic RNA leading to ΔTas carries all features necessary for successful packaging and reverse transcription, ΔTas infects new cells where it integrates. ΔTas has been found *in vitro* and also *in vivo* in a rabbit infection model and in the monkey to a considerable extent.^{19,54,208,209} ΔTas provirus is replication incompetent because of its *tas* gene deletion; however, it is not transcriptional silent. Owing to the basal activity of the IP (see later discussion), there is still some residual *bet* gene expression. The magnitude of viral transcription depends on the number of integrated copies of ΔTas and probably also depends on the site of integration where cellular promoter/enhancer elements could augment levels of Bet mRNA.²⁰⁹ Cells expressing *bet* become resistant to superinfection by homologous virus—a feature that has so far not been further investigated.^{15,209} Furthermore, a role in promoting viral persistence has been discussed for Bet in general and ΔTas in particular.^{155,209} Functionally, ΔTas behaves like a defective interfering (DI) genome. However, whether the typical oscillating frequency of DI viruses occurs with ΔTas has not been investigated.

Because only either Bet or Tas can be made, and because FV gene expression starts with the translation of Tas protein (see later discussion), it has been speculated that Bet synthesis represents the molecular switch, which determines viral latency.¹⁵⁵

REGULATION OF GENE EXPRESSION

FV gene expression (see Fig. 52.6) begins with expression of the *tas* and *bet* genes directed by transcripts initiated at the IP located in the *env* ORF.^{139,140} This is mediated by the weak basal transcriptional activity of the IP, whereas the U3 promoter in the LTR of the provirus has no, or almost no, similar activity.^{109,139}

In FFV, enhancer elements upstream of the IP implicated in its basal transcriptional activity include sites for SP-1^{16,258}; however, their biological function has not been characterized in any depth. In BFV, AP-1 sites in this location have been partially characterized²⁶¹ and may control the basal gene expression that it directs.

As a consequence of the IP's low basal activity, some Tas protein is made, which subsequently binds with high affinity to specific DNA elements—namely, Tas binding sites (TBS) upstream of the IP—resulting in a positive feedback loop of

tas gene expression. Once sufficient amounts of Tas have been synthesized by this mechanism, Tas, with lower affinity but higher avidity, binds to upstream promoter elements in the 5' LTR U3 region. This then leads to the expression of structural genes and, to some extent, also to LTR-directed *tas* and *bet* gene expression.^{16,137}

The IP and LTR U3 TBS essential for Tas-mediated transactivation have been determined and characterized in detail (e.g., by electromobility shift assays) for PFV, SFVmac, FFV, and BFV (see Table 52.2). However, no real TBS consensus sequence has emerged. Furthermore, even within a specific FV species, the IP and U3 TBS show only very weak homology. In general, it can be noted that the finer details of Tas-mediated regulation of FV gene expression remain to be elucidated.

Similar to other complex retroviruses, FVs encode a regulatory protein acting at the transcriptional level. A *post*-transcriptional regulator, such as Rev of HIV or Rex of PTLV, has never been identified in FVs. The peculiarities of FV gene regulation—one transcriptional activator and two active promoters—allow for a biphasic mode of FV gene expression analogous to other complex retroviruses.³⁹ However, this does not circumvent a central problem of all retroviruses: regulation of nuclear export of intron-containing mRNAs containing functional splice sites.³⁸ As detailed elsewhere in this book (see Chapters 48 and 49), complex retroviruses solve this problem by interacting with the karyopherin CRM1 by using a viral regulatory protein, which binds to an RNA secondary structure embedded in viral mRNAs. In contrast, some simple retroviruses utilize the NXF1/NXT1-mediated cellular mRNA export pathway by means of a constitutive transport element (CTE) located within their genomic mRNAs.³⁸ PFV (pre-) genomic and Gag encoding mRNA appears to make use of yet another so far undisclosed pathway.²¹ Nuclear export of FV RNA is, on one hand, CRM1 dependent and, on the other, relies on the presence of additional cellular proteins. The host cell HuR protein binds to the unspliced PFV (pre-) genomic RNA, and two cellular adapter molecules, ANP32A and ANP32B, mediate the interaction between the RNA-bound complex and CRM1.^{16,21} The FV RNA elements in question have not yet been characterized. The consequences of this viral nuclear RNA export mechanism on the synthesis of early response cellular proteins, whose mRNAs normally use this export pathway, are unknown. It is tempting to speculate that FVs, by making use of a nuclear mRNA export pathway involving cellular proteins also required for the synthesis of early response proteins, may outcompete the latter.

CIS-ACTING RNA SEQUENCES AND PACKAGING OF RNA

FV packaging of (pre-) genomic RNA is quite different from that of orthoretroviruses: Three *cis*-active RNA elements (CAS I–III) essential for viral replication have been identified and partially characterized by their capacity to enable an efficient FV vector gene transfer¹³² (see Fig. 52.6).

The first region, CAS-I, is located in the 5' untranslated leader of the viral (pre-) genome and extends into the *gag* gene. It harbors the R-U5 region of the LTR, the PBS, and what is believed to be the ψ -sequence.¹³² The R region also contains the elements conferring dimerization of the (pre-) genomic RNA.^{29,53}

The second element, CAS-II, is located within the 3' half of the *pol* gene^{52,82,177,260} (see Fig. 52.6). It is mainly the presence of and requirement for CAS-II that sets FV (pre-) genomic RNA and Pol protein incorporation apart from orthoretroviral particle assembly. CAS-II is believed to harbor (in 5' to 3' direction) sequences for packaging of viral RNA¹⁷⁷; for encapsidation of the Pol polyprotein¹⁷⁷; the PARM sequence required to activate the FV PR⁷⁵; and the cPPT, which is probably engaged in efficient reverse transcription.¹⁷⁶ Furthermore, one of the RNA elements directing nuclear export via HuR appears to be located in CAS-II.²¹ These, however, are not required for efficient FV vector transfer. RNA sequences of the individual functional elements may partially overlap and mediate more than one function. Intervening sequences can be deleted without apparent loss of vector transfer function.²⁵⁵

The third element, CAS-III, is located far downstream on the viral (pre-) genome. It contains the 3' PPT and the LTR (U3-R) sequences needed for reverse transcription and integration as well as transcription initiation and polyadenylation upon proviral integration¹³² (see Fig. 52.6).

OVERVIEW OF THE VIRUS LIFE CYCLE

The Early Phase: Establishing the Provirus

FVs bind to yet unknown, probably ubiquitously expressed and evolutionary conserved, cellular receptor molecules (Fig. 52.14). Proteoglycans contribute to FV entry but do not appear to be the major cellular receptor.^{210a,230} Uptake of most FVs predominantly seems to involve endocytosis and a pH-dependent FV Env-mediated fusion process, although PFV Env displays a significant fusion activity at neutral pH.¹⁸⁰ After release into the cytoplasm, FV capsids migrate along the microtubular network to the centrosome, where they accumulate.²¹⁰ At the centrosome, intact FV capsids can remain functional active for weeks in G₀-resting cells, allowing productive infection to proceed upon re-entry of targets cells into the cell cycle.¹²⁶ It is generally agreed upon that mitosis is required for FV replication and that the latency period from cell entry to integration and gene expression, owing to the facultative viral DNA genome, can be very long.^{13,43,126,173,245} Most productive infections are attributed to FV particles that have reverse transcribed their viral RNA (pre-) genome prior to target cell infection.^{150,160} However, some genome reverse transcription takes place upon FV host cell entry and seems to add to viral infectivity predominantly under conditions of low MOI.^{42,270} Disassembly of FV capsids accumulated at the centrosome is reported to involve Gag cleavage by viral and cellular proteases in a cell-cycle-dependent manner.^{66,75,125} Upon mitotic breakdown of the nuclear membrane, the viral DNA and fragments of Gag then gain access to the chromosome, whereas active nuclear import of Gag into interphase nuclei is not observed.¹⁶¹ Productive viral replication requires insertion of the provirus into the host genome mediated by the viral integrase,^{50,153} although nonintegrated viral DNA appears to be transcriptionally active, similar to reports of orthoretroviruses.⁴³ Like other retroviruses, there are no preferred sites of FV integration. Analyses of FV integration patterns have revealed no preference for actively transcribed genes and a much lower frequency of integration into the proximity of cellular promoters than MLV.^{168,247}

FIGURE 52.14. Overview of the prototype foamy virus replication cycle (see text for details). (Modified from Lindemann D, Rethwilm A. Foamy virus biology and its application for vector development. *Viruses* 2011;3:561–585.)

The Late Phase: Generation of Progeny Viruses

Like orthoretroviruses, FVs exploit the cellular transcription machinery for viral transcription. FV transcription is special, as a cascade of events is launched by the action of two viral promoters and one transcriptional transactivator. FV nuclear RNA export also appears to be unique.

The Gag and Pol proteins, as well as the accessory gene products Tas and Bet, are translated on free ribosomes in the cytoplasm. The Env protein is targeted to the secretory pathway by ribosomal translation in the rough endoplasmic reticulum and displays a highly unusual biosynthesis and membrane topology.^{130,257}

FV capsid assembly follows a retrovirus type B/D morphotype strategy. This includes the microtubule-dependent transport of Gag proteins to the centrosome involving a CTRS within Gag.^{46,265} A Gag CC domain mediates FV capsid preassembly at the centrosome.²⁴⁰ Unlike orthoretroviruses, FV capsids lack membrane-targeting signals. Virion budding and egress requires co-expression of the viral Env protein. This process involves a highly specific interaction between the viral glycoprotein complex and capsid proteins. This interaction, mediated by an N-terminal region in the capsid and the CyD of the envelope LP subunit,^{32,130,257} presumably takes place at the *trans*-Golgi network (TGN).²⁶⁵ Together with the involvement of the cellular VPS machinery in FV particle release, this is suggestive for an exocytotic budding pathway.^{130,265} However, there are also clear indications for budding of FVs at the plasma membrane.¹¹⁹

Although the exact time point of reverse transcription with respect to capsid assembly and maturation is unknown, preassembled intracellular FV capsids contain significant amounts of reverse transcribed, infectious viral genomic DNA.^{150,160,203,221,269} In this respect, FVs show a similarity to HBV replication (see Chapter 68). Gag, but not Pol precursor protein cleavage, is a prerequisite for intraparticle reverse transcription that occurs late in the FV replication cycle.^{48,202}

Orthoretroviruses can occasionally behave like retrotransposons and reshuttle their genome to the nucleus without an extracellular phase. The frequency of such intracellular retrotransposition (IRT) has been estimated to be 1 per 10^6 proviruses and is thought to reflect the frequency at which the RNA genome is prematurely reverse transcribed.^{80,203} For PFV, this frequency is much higher (approximately 5%)—a finding concordant with late reverse transcription of the RNA (pre-) genome.⁸⁰ It was subsequently found that IRT strongly depended on the cell type used for analysis and on the particular FV isolate.^{81,203} Thus, IRT is not a general phenomenon of FVs. However, the late phase of reverse transcription of the RNA (pre-) genome is required for this process.

APATHOGENICITY OF FOAMY VIRUSES

Apart from very rare reports of subclinical laboratory findings, *in vivo* infections by FVs follow a benign course. Asking the

reason for this is probably posing the wrong question. The pathogenicity of an infectious agent requires an explanation, not the apathogenicity of what has been called a “perfect parasite”²⁴⁹ whose only “interest” is to multiply its genome without doing harm. It appears that FVs evolved over millions of years to do exactly this.

Certainly, some arguments can be made in favor of this hypothesis. The site of active replication *in vivo* determines to a large extent the pathogenicity of an infectious agent. FVs appear to replicate only in cells that are destined to be eliminated (e.g., the oral mucosa and occasionally the intestine). However, during the establishment of persistence, it is likely that lymphocytes become infected and produce low amounts of virus that disseminate throughout the body. Once persistence is established, FV genes may no longer be expressed in lymphocytes. A second factor contributing to the benign character of FV infections is that the Tas transactivator appears to be specific for its autologous cognate viral promoters. The off-target activation of gene expression is probably a rare event. Pleiotropic effects, as they occur with PTLV-I Tax (see Chapter 48), does not occur. Furthermore, the integration of FVs does not induce the activation of cellular oncogenes because they lack strong enhancer elements. In addition, a strong polyadenylation signal in the LTR seems to prevent a read-through of viral transcripts into cellular genes for activation.^{84,216}

FOAMY VIRUS VECTOR APPLICATIONS

There are several advantages that FV vectors have over the more common orthoretroviral vectors (summarized in Table 52.3). FV vectors have been shown to be extremely useful in transducing stem cells of hematopoietic or mesenchymal origin.^{128,255} The same targets are transduced with at least the efficiency of HIV-1 vectors pseudotyped with the glycoprotein of vesicular stomatitis virus (VSV-G). However, even better transduction and engraftment rates of hematopoietic stem cells have been observed when a mutant of the FV *env* gene, deficient in LP ubiquitination and optimized for expression in human cells, is used to pseudotype HIV-1 vectors (H. Hanenberg, Indianapolis, Indiana, personal communication).

TABLE 52.3	Advantages of Foamy Virus Vectors Compared with Ortho-/gammaretroviral Vectors
<ol style="list-style-type: none">1. Derived from nonpathogenic parental viruses2. Transduction of stem cells with exceptional high efficiency3. Favorable integration profile4. No evidence of oncogene activation in relevant animal models5. Possibility of particle concentration6. No gene silencing7. Relatively stable DNA genome8. Large capacity to accommodate foreign genes9. Natural of self-inactivating type, use of tissue-specific promoters permitted10. Efficient pseudotyping of orthoretroviral vectors by modified foamy virus Env	

Basically, FV vector applications follow the field of gammaretroviral and lentiviral vectors using the same models of single gene defects that can be corrected by gene transfer into hematopoietic or mesenchymal stem cells. However, two models are well advanced and may lead to human clinical trials in the near future. One is the replacement of a defective *cd18* gene. CD18 is essential for leukocytes to adhere to endothelial cells and to migrate from the blood stream to sites of infection. The CD18 defect results in a disease known as leukocyte adhesion deficiency (LAD). Canine LAD has been successfully treated in a clinically relevant large animal dog model⁹; the recipient animals have been followed for more than 4 years of age and are clinically completely healthy.¹⁶⁹

The other disease is Fanconi anemia (FA). FA results from a defect in double-strand DNA breakage repair. There are 16 so-called complementation groups known, because at least 16 genes can be defective. Probably some more very rare variants remain to be discovered. *Fanca* and *fancc* defects account for approximately two-thirds of the cases. Large animal models of the disease are not available. However, knockout mice for some of the genes have been successfully treated on a NOD/SCID background by transfer of gene-corrected human hematopoietic stem cells.²²⁵ The repopulating cells have been serially transferred documenting their stem cell character.²²⁵ A forthcoming clinical trial to combat FA will rely on HIV-derived vectors pseudotyped with a PFV-derived envelope.⁶⁸

These rare life-threatening diseases serve as model systems for more common conditions. Therefore, one may speculate about tackling more widespread diseases with these apparently benign vectors in the future.

PERSPECTIVES

In the past few years, FV research has resulted in several new findings that impact on fundamental aspects of retrovirus

TABLE 52.4	Some Future Foamy Virus Research Topics

FV, foamy virus.

replication. It is likely that future studies of FVs will unravel new aspects of these pathways. Some topics worth investigating have already been alluded to in this text and are summarized in Table 52.4. Aside from basic research into FV replication and necessary *in vivo* and *ex vivo* studies (e.g., cellular immune responses to FVs), increasing interest will focus on the use of FV-derived vectors. To cover this aspect, the reader is referred to more specialized reviews.^{132,188,246}

Perspective

Polyomaviruses are composed of nonenveloped capsids with a simple, double-stranded DNA (dsDNA) genome of approximately 5,000 base pairs containing a single origin of replication and a bidirectional promoter that drives expression of messenger RNA (mRNA) transcripts encoding five to nine proteins. The small size of the polyomavirus genome, comparable to a simple plasmid, and its limited number of genetic elements have enabled research that continues to be at the forefront of biology including DNA replication, gene expression, signal transduction, and oncogenesis.

The history of polyomavirus research began in the 1950s when Ludwig Gross¹⁰³ noted that when he passaged a mouse leukemia virus in mice, the recipients occasionally developed salivary and parotid gland tumors rather than leukemia. He isolated this specific activity and demonstrated that the parotid agent differed from murine leukemia virus (MLV) in its sedimentation, filtration, and heat stability properties. Stewart et al²⁴⁷ observed the formation of multiple tumor types in newborn mice inoculated with this agent and coined the name *polyomavirus*, derived from the Greek word *poly*, meaning “many,” and *oma*, denoting “tumor.” The mouse polyomavirus is often called simply “polyomavirus” but will be referred to as MPyV in this chapter, consistent with the most recent taxonomic classification (Table 53.1).¹²⁸ Initially discovered at the same time as MPyV, murine pneumotropic virus (MPtV), also known as Kilham virus or K virus, causes severe interstitial pneumonia in newborn mice.^{101,144}

The next member of the family to be isolated was simian virus 40 (SV40) by Sweet and Hilleman²⁵⁶ in 1960. They were screening samples from poliovirus vaccine lots produced in rhesus monkey kidney cells for the presence of contaminating viruses. SV40 was the 40th virus isolated in this screen and caused cytopathic or vacuolating effects in African green monkey kidney cells but not in the rhesus monkey cells used for vaccine production. It soon became clear that the early production batches of poliovirus vaccine were contaminated with SV40. Although the Salk poliovirus vaccine was inactivated by formalin treatment, SV40 was relatively resistant to this treatment and survived. The presence of SV40 in the vaccine quickly became a public health concern when the oncogenic potential of purified virus was demonstrated in newborn hamsters.

Since that time, many polyomaviruses have been isolated from a variety of mammalian and bird species. The first two human polyomaviruses, JC (JCPyV) and BK (BKPyV), were isolated in 1971 from immunocompromised patients. JCPyV was isolated by the transfer of brain tissue from a patient with the demyelinating disease progressive multifocal leukoencephalopathy (PML) into cultures of human fetal brain tissue.¹⁹⁹ BKPyV was isolated from the urine of a renal

HISTORY

Polyomaviruses are found ubiquitously in a broad range of avian and mammalian species. Polyomaviruses can cause severe illness and death on an epidemic scale in birds. In contrast, polyomaviruses typically cause lifelong and asymptomatic infections in healthy humans but severe illness in immunocompromised patients. Recognition of the ubiquitous presence of polyomaviruses in their natural hosts as well as their disease-causing ability has prompted a variety of research efforts.

transplant patient after inoculation into African green monkey kidney cells.⁸⁹

The advent of advanced molecular biology techniques including polymerase chain reaction (PCR), rolling circle amplification, and deep DNA sequencing led to the identification of seven additional human polyomaviruses. WUPyV and KIPyV were cloned from respiratory secretions of young children by investigators at Washington University and the Karolinska Institute, respectively. The discovery of Merkel cell polyomavirus (MCPyV) reflected recognition that the incidence of Merkel cell carcinoma, a rare form of skin cancer, was more frequent in severely immunocompromised patients, suggesting an infectious cause.⁷¹ MCPyV was recovered from Merkel cell carcinomas by digital transcriptome subtraction, a method that used high-throughput sequencing of cellular transcripts to identify sequences that did not match the human genome but were distantly related to BKPyV.⁷⁸ Two additional polyomaviruses, HPyV6 and HPyV7, were cloned from the skin or hair follicles of healthy adults using a technique called rolling circle amplification that takes advantage of the small circular nature of the polyomavirus dsDNA genome.²²⁶ Using the same technique, trichodysplasia spinulosa-associated polyomavirus (TSPyV) was found in a patient with a rare skin disease named trichodysplasia spinulosa.²⁶⁸ HPyV9 was identified in the serum of a renal transplant patient and on the skin of a patient with Merkel cell carcinoma.^{222,227} Undoubtedly, additional human polyomaviruses will be discovered. Although identification of novel polyomaviruses by DNA sequencing has become easier, isolation of virion particles remains a technical challenge.

Primate polyomaviruses from Old World monkeys include the simian agent 12 (SA12), isolated from a South African vervet monkey kidney culture in 1963, and B-lymphotropic polyomavirus (LPyV), isolated from an African green monkey lymphoblast cell line, as well as polyomaviruses directly isolated from animals including Bornean (OraPyV1) and Sumatran orangutan polyomavirus (OraPyV2), gorilla polyomavirus (GggPyV), and chimpanzee polyomavirus (CHPyV).¹⁶⁰ The first New World monkey polyomavirus was isolated from squirrel monkey (SqPyV2).²⁷²

In addition to MPyV and MtPyV, a number of nonprimate mammalian polyomaviruses have been identified. Hamster polyomavirus (HaPyV) was discovered in a spontaneously occurring hair follicle epithelioma from a Syrian hamster. This is an interesting member of the polyomavirus family because the behavior of the virus in the tumors most closely resembles that of the papillomaviruses in that viral particles can be found in the highly differentiated layers of the tissue. However, analysis of the HaPyV DNA sequence and its genome organization revealed that it is indeed a polyomavirus and most closely related to MPyV.⁶¹ Rabbit kidney vacuolating virus (RKV) was originally isolated from a rabbit papilloma but was shown to be involved in subclinical infections in rabbits. Bovine polyomavirus (BPvV) contains the smallest of the polyomavirus genomes with fewer than 4,700 base pairs. Sea lion polyomavirus (SLPyV) was isolated from a sick animal with kidney swelling, interstitial nephritis, and an intestinal lymphoma.⁴⁶

Polyomaviruses have been isolated from several bird species. The first of these, budgerigar fledgling disease virus (BFDV), was isolated from a parakeet in 1986.¹⁹⁰ Unlike the strict host range restriction of mammalian polyomaviruses, BFDV can infect and cause disease in a wide variety of bird species and is now referred

to as avian polyomavirus (APyV). Recently identified bird polyomaviruses include canary (CaPyV), crow (CPyV), finch (FPyV), and goose hemorrhagic polyomavirus (GHPyV).^{105,129,131} In general, the avian polyomaviruses cause a severe inflammatory illness that often results in death. For example, infection with GHPyV causes hemorrhagic nephritis and enteritis.¹³⁰

For many years, the polyomaviruses were studied principally as model systems for understanding basic eukaryotic cell processes including DNA replication, RNA transcription, splicing and processing, and oncogenic transformation. The cloning and sequencing of the SV40 genome ushered in the era of recombinant DNA research. Indeed, the SV40 genome may be the most intensively studied DNA molecule per base pair. Several genetic elements from the SV40 genome are used in nearly every molecular biology laboratory in the world today.²⁰⁸

Interest in the polyomaviruses as human pathogens lagged behind these more basic biological studies because for many years the incidence of polyomavirus-associated diseases was rare and not well recognized. The onset of the human immunodeficiency virus type 1 (HIV-1)/acquired immunodeficiency syndrome (AIDS) epidemic, however, led to a dramatic rise in the incidence of PML, a JCPyV-induced disease. In addition, recent advances in immunosuppressive regimens for bone marrow and solid organ transplant recipients and biological therapies for autoimmune diseases led to increases in JCPyV-, BKPyV-, and TSPyV-associated diseases. More recently, the apparent transforming activity of the MCPyV and its contribution to Merkel cell carcinoma has generated widespread interest in the polyomaviruses. Studies have led to the emerging view that while many polyomavirus features are shared, there are many fundamental differences that distinguish each virus.

CLASSIFICATION

Polyomaviruses were originally classified within the *Papovavirus* family that included *papillomavirus*, *polyomavirus*, and *vacuolating virus*.¹⁸¹ The vacuolating or cytopathic effect of SV40 virus on host cells during lytic infection led to this distinction. Polyomaviruses were split from the papillomaviruses in 2000. Recently, a proposed classification organized polyomaviruses into three genera based on the DNA sequence of the viral genome and its normal host. The genera *Orthopolyomavirus* and *Wukipolyomavirus* contain polyomaviruses isolated from mammalian species, while *Avipolyomavirus* contains all avian species (Fig. 53.1).¹²⁸ The *Wukipolyomavirus* genus contains WUPyV, KIPyV, HPyV6, and HPyV7, and the *Orthopolyomavirus* genus contains all other polyomaviruses including the bandicoot papillomatosis carcinomatosis virus type 1 (BPCV1) and type 2 (BPCV2).

Several polyomaviruses have not been officially classified within the family because the complete viral genomic sequence is not available. These include the baboon polyomavirus 2 (BPvV2), RKV, athymic rat polyomavirus (RatPyV), and cynomolgus polyomavirus (CyPV).

VIRION STRUCTURE

Polyomavirus virions are nonenveloped, 45- to 50-nm particles consisting of three virally encoded capsid proteins, VP1, VP2,

FIGURE 53.1. Phylogenetic relationships among the *Polyomaviridae* family based on whole genomic nucleotide sequences. The mammalian polyomaviruses are contained in the *Orthopolyomavirus* and *Wukipolyomavirus* genera, while the bird polyomaviruses are contained in the *Avipolyomavirus* genus. See Table 53.1 for full names and Genbank accession numbers. (Reproduced from John R. Buck CB, Allander T, et al. Taxonomical developments in the family Polyomaviridae. *Arch Virol* 2011;156(9):1627–1634, with kind permission from Springer Science+Business Media.)

and VP3, containing a circular dsDNA genome wrapped with cellular histones H2A, H2B, H3, and H4.²⁶² The virion minichromosome exhibits the same nucleosome structure as cellular chromatin except for the absence of histone H1 that becomes associated with the viral genome only when in the infected cell. The particles have a $T = 7$ icosahedral symmetry and sediment at 240S in sucrose density gradients (Fig. 53.2). The density of mature virions is 1.34 g/mL and of empty capsids is 1.29 g/mL, as determined by cesium chloride equilibrium gradient centrifugation. The polyomaviruses are relatively resistant to heat

FIGURE 53.2. Composite electron micrograph of a 40-nm polyomavirus icosahedral structure derived from assembly of VP1, negatively stained with 2% phosphotungstic acid (50,000 \times).

and formalin inactivation, demonstrated by the isolation of viable SV40 from the Salk poliovirus vaccine.⁵¹ Because polyomaviruses are nonenveloped, they are resistant to lipid solvents. Similar to most viruses, preparations of polyomavirus virions contain many different types of particles. For example, in addition to mature virions, one can find empty capsids and capsids that contain cellular, rather than viral, DNA.

The polyomavirus capsid contains 360 molecules of VP1 arranged in 72 pentamers or capsomeres each containing 5 molecules of VP1 and 1 molecule of VP2 or VP3. Only the VP1 molecule is exposed on the surface of the capsid. The icosahedral capsid has both five- and sixfold axes of symmetry, with 12 pentamers surrounded by 5 other pentamers and 60 pentamers surrounded by 6 pentamers (Fig. 53.2). Capsomeres with fivefold symmetry are unusual but supported by the high-resolution structure of SV40.^{166,246} The C-terminus of each VP1 molecule extends out of the pentamer and contacts the neighboring capsomere. This structure is flexible and thereby provides the means to form an icosahedron. Capsomere contacts are stabilized by the presence of calcium ions, and mutations in residues that bind calcium result in premature disassembly.¹⁶⁵ Treatment of virus with EGTA under reducing conditions results in the dissociation of the capsid into VP1 pentamers. In addition to VP1, VP2, and VP3, APyV expresses VP4 (agnoprotein 1a) that interacts with the C-terminus of VP1 and may be incorporated into viral capsids.²³⁴ The capsid contains posttranslational modifications including disulfide bridges that form between the pentameric capsomeres. In addition, VP2 undergoes myristoylation at its N-terminus. A recent report found a large number of posttranslational modifications on the BKPvV VP1 protein, although the role of these modifications during infection is not known.⁷⁴

GENOME STRUCTURE AND ORGANIZATION

The polyomavirus dsDNA circular genome contains approximately 5,000 base pairs and can be divided into three parts: the

FIGURE 53.3. Genome organization for simian virus 40 (SV40), mouse polyomavirus (MPyV), bandicoot papillomatosis carcinomatosis virus type 1 (BPCV1), and avian polyomavirus (APyV). All polyomaviruses express large T (LT) and small T (ST) antigen from the early region (counterclockwise arrows). MPyV also expresses middle T (MT) antigen. The late region (clockwise arrows) expresses the viral coat proteins VP1, VP2, and VP3 for SV40, MPyV, and APyV. SV40 also expresses a variably spliced small protein called VP4. BPCV1 expresses L1 and L2 coat proteins. At the 5' end of the late transcript, SV40 expresses agnoprotein, while APyV expresses VP4. APyV late region expresses two transcripts that encode all late proteins.

early region encoding genes that are expressed prior to the onset of DNA replication; the late region encoding genes expressed after viral DNA replication commences; and the regulatory region, containing the origin of DNA replication as well as the promoters for early and late viral genes (Fig. 53.3). The early and late promoters give rise to primary transcripts from opposite strands of the DNA. The regulatory region including the origin is often referred to as the noncoding control region (NCCR). The numbering system for the polyomavirus genome differs from virus to virus with nucleotide position 1 defined in different ways.²⁶² There has been precedent in recent years, however, to call the nucleotide preceding the A in the large T antigen ATG nucleotide 1, with numbering proceeding in the late direction, that is, away from the large T antigen open reading frame.

The small size of the polyomavirus genome made it amenable to classical genetic approaches.²⁶² Infection with temperature-sensitive mutants of SV40 led to the identification of five complementation groups, A, B, BC, C, and D. Mutations in group A mapped to the large T antigen gene; groups B, BC, and C to the *VP1* gene; and group D to the *VP3* gene. MPyV mutants have been classified into similar complementation groups, although no standard nomenclature was developed for this virus. Other mutants of MPyV known as host range (hr-t) mutants were selected for their inability to grow in established cell lines but retained the ability to replicate in primary cells or transformed cells. These mutations were later mapped to the middle T and small T antigen genes.²⁴⁰ The analysis of these early mutants set the stage for detailed and directed mutational studies enabled by recombinant DNA technology.

Another early genetic approach to the study of polyomaviruses was the selection for so-called evolutionary variants. In these experiments, viruses were passaged at high multiplicities of infection and variants were isolated. Many of these variants had alterations in the regulatory region that imparted a growth advantage to the virus. Passage of polyomavirus in culture often leads to duplications, deletions, and other rearrangements in the regulatory region.¹⁸⁵ Although high-multiplicity passage of JCPyV in human glial cell cultures does not result in alterations in the regulatory region, the regulatory regions of BKPyV and JCPyV are frequently found to be rearranged when isolated from diseased tissues or patients' blood.

The polyomavirus early and late promoters are contained within the regulatory region and overlap each other as well as the origin of replication. Early transcription progresses from the early promoter around the genome in one direction. Late transcription proceeds from the late promoter around the genome in the opposite direction. The early mRNAs are produced by posttranscriptional processing at a polyadenylic acid or poly(A) tail site that is located about halfway around the circular genome from the start site and by removal of introns by the cellular splicing machinery. SV40 was one of the first experimental systems where it was demonstrated that RNA polymerase II transcribes past the 3' end of the mature mRNA molecule, implying that the 3' end, including the poly(A) tail, was generated posttranscriptionally.⁸²

Each of the polyomaviruses encodes at least two early mRNAs by alternative splicing that are translated into the large T and small T antigens (Fig. 53.4). MPyV and HaPyV produce a third alternatively spliced mRNA that codes for middle

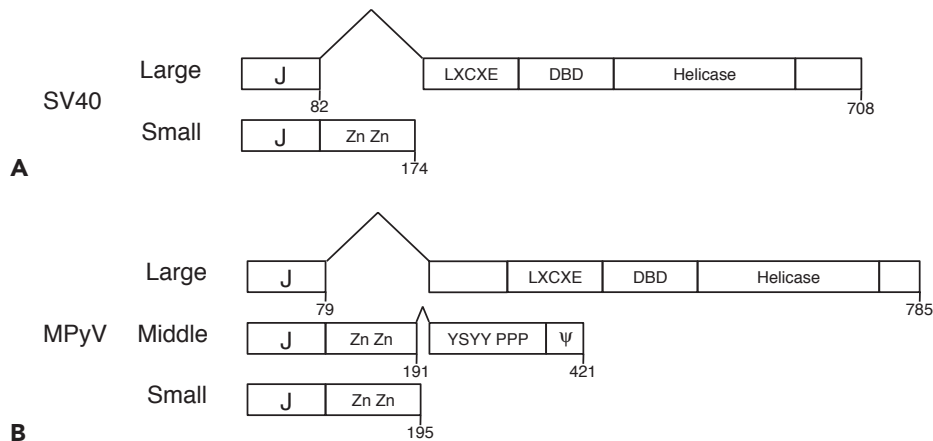

FIGURE 53.4. Simian virus 40 (SV40) (A) and mouse polyomavirus (MPyV) (B) T antigens. The N-terminal J domain is shared with all T antigens. SV40 expresses large and small T antigens and MPyV expresses large, middle, and small T antigens. The large T antigens contain the LXCXE motif that binds directly to RB1, a DNA-binding domain (DBD) that binds to the origin of replication, and a helicase domain. The small T antigens contain a unique domain not shared with large T antigen that binds to two Zn molecules. The MPyV middle T antigen shares the J domain and Zn-binding domain with small T antigen and also contains tyrosine and serine residues (YSY) that become phosphorylated, a proline-rich region, and a C-terminal hydrophobic domain.

T antigen. The “T” in T antigen derives from the initial identification of these proteins as tumor antigens that were recognized by antisera from tumor-bearing animals inoculated with SV40.^{21,107} For many years, it was believed that large, middle, and small T antigens were the only early transcripts, but more recently it has been demonstrated that these viruses encode additional early mRNAs that differ in their splicing patterns, particularly for large T antigen. In SV40 and MPyV, an additional mRNA encodes a protein called 17KT and tiny T, respectively. Similarly, JCPyV produces a series of alternatively spliced mRNAs that encode proteins referred to as T’135, T’136, and T’165, and BKPyV encodes a molecule called truncated TAg. MCPyV encodes a full-length, 816-residue large T antigen as well as an alternatively spliced 57-kD T antigen that corresponds to the first 440 and last 100 residues of the full-length large T antigen.²³⁷

The late mRNA is transcribed in the opposite direction from the early mRNAs. As with the early transcripts, the late transcript has a single poly(A) site approximately halfway around the genome and is alternatively spliced (Fig. 53.3). The polyomavirus late transcript encodes three capsid proteins, VP1, VP2, and VP3. Notably, VP3 is translated in the same open frame as VP2 but uses an alternate AUG start codon downstream of the VP2 start codon and thereby shares all residues with VP2. In addition, SV40 encodes a VP4 protein that uses an internal AUG start codon even further downstream from VP3 and functions as a viroporin that promotes virus release from the infected cell.²¹² The late region transcript from SV40, JCPyV, and BKPyV as well as SA12, BatPyV, BPvV, SLPyV, and SqPyV encode an additional protein called agnoprotein.

Avian polyomaviruses express early transcripts encoding large and small T antigen, but the late transcripts have several distinct features (Fig. 53.3). There are two late transcription start sites, PL1 and PL2, that give rise to at least eight different transcripts due to alternative splicing.¹⁶⁴ PL1 encodes two forms of VP4 (agnoprotein 1a) and VP4d (VPΔ4, agnoprotein 1b), while PL2 gives rise to two forms of agnoprotein 2a and

2b that use the same splice sites as VP4 and VP4d but are translated in a different reading frame. Avian agnoprotein 2a and 2b bears some similarity to the SV40 agnoprotein. All of the late avian transcripts also encode for VP1 or VP2 and VP3.

The late strand of several polyomaviruses encodes a microRNA (miRNA).^{39,253} The SV40 miRNA maps just 3' of the late poly(A) site and appears to correspond to SAS (SV40-associated small RNA), a small RNA molecule identified 25 years earlier, albeit of then-unknown function. These miRNAs are complementary to the early mRNAs, target the early mRNAs for degradation, and may serve to limit the expression levels of the T antigens. MiRNA have been identified in SV40, BKPyV, JCPyV, MCPyV, SA12, MPyV, BPCV1, and BPCV2.³⁹

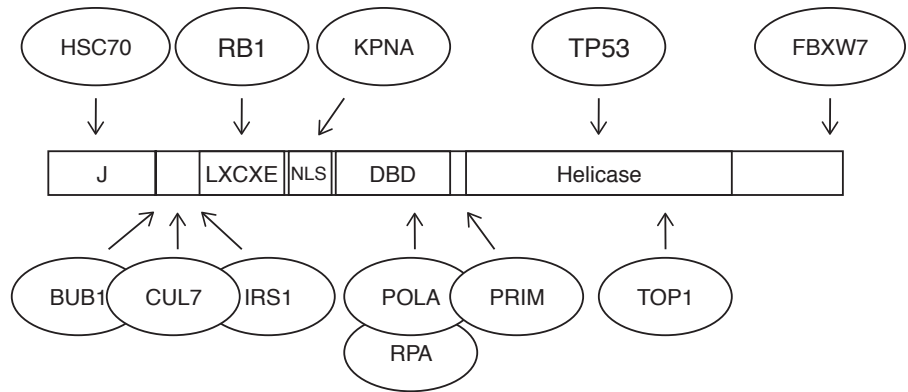

Structure of T Antigens

Much of what is known about the structure of polyomavirus T antigens comes from studies of SV40. All polyomavirus T antigens share an N-terminal region of approximately 80 residues that shows structural and sequence homology to the DnaJ or J domain found in host cell HSP40 homologs (Fig. 53.4). Full-length large T antigen is a nuclear phosphoprotein of approximately 700 residues. The molecule’s atomic coordinates have been assembled from crystallography of isolated domains, including the DnaJ and the retinoblastoma protein-binding domains; the DNA-binding domain, also known as the origin-binding domain; and a central domain consisting of residues 251 to 627 that forms a hexamer and contains the adenosine triphosphatase (ATPase) and helicase activities required for viral replication.¹⁶³ Studies using scanning transmission electron microscopy, negative staining with atomic force microscopy, and single-particle reconstruction of cryoelectron microscopy (cryo-EM) images revealed that large T antigen forms a double hexamer in a head-to-head arrangement when bound to the origin of DNA.⁵⁰

A number of functional domains contained within large T antigen are required for viral replication. Functions intrinsic to SV40 large T antigen include the ATPase/helicase domain and

FIGURE 53.5. Simian virus 40 (SV40) large T antigen binds to cellular host proteins.

The J domain binds to HSC70, the LXCXE motif binds to RB1, the helicase domain binds to TP53, and the phosphorylated threonine residue 701 binds to FBXW7. The cellular proteins BUB1, CUL7, and IRS1 bind to a region between the J domain and the LXCXE motif. Karyopherin (KPNA) binds to the nuclear localization sequence (NLS). Large T antigen recruits replication protein A (RPA), topoisomerase 1 (TOP1), DNA polymerase α (POLA), and primase (PRIM) to promote viral DNA replication.

the DNA-binding domain that mediates direct interactions with specific DNA sequences at the origin of replication. In addition to these intrinsic functions, the SV40 large T antigen domains serve to recruit host factors important for viral replication (Fig. 53.5). For example, the N-terminal J domain, containing the canonical residues HPDK, binds and activates the ATPase activity of host cell HSC70.³¹ The DNA-binding domain binds to replication protein A, while the helicase domain binds to the DNA polymerase α /primase complex.¹¹⁸ In addition, the helicase domains of many but not all polyoma large T antigens bind to p53. The outer surface of each SV40 large T antigen hexamer subunit can bind directly to the DNA-binding domain of p53.¹⁶⁷ The large T antigen from MPyV is a notable exception among polyomaviruses because it does not bind to p53, although the ability of all the other polyomavirus large T antigens to bind to p53 has not yet been reported.

Smaller functional motifs within large T antigen include the nuclear localization signal (NLS).^{132,154} Mutations that disrupt the NLS result in the cytoplasmic localization of SV40 large T antigen and inability to support the viral lytic life cycle. All mammalian polyomavirus large T antigens contain the conserved residues LXCXE (where X is any residue) that bind directly to the retinoblastoma family of tumor suppressor proteins including pRb (RB1), p107 (RBL1), and p130 (RBL2).^{60,68} The large and small T antigens from GHPyV, CPyV, and FPyV each contain the LXCXE motif, while those from APyV contain a related sequence, LXAXE. It is not known if any of the bird polyomavirus T antigens can bind to pRb or p53.

SV40 large T antigen contains a series of posttranslational modifications, including phosphorylation, O-glycosylation, acylation, poly(ADP)-ribosylation, and acetylation. In addition, phosphorylation of C-terminally located threonine residues in SV40 large T antigen creates a phospho-degron motif that binds directly to FBXW7, an F-box substrate adapter. Large T antigen binding to FBXW7 blocks binding to cyclin E and prevents its degradation by the CUL1^{FBXW7} RING ubiquitin ligase (Fig. 53.5).²⁷⁷ Phosphorylation regulates some of the functions of the molecule, including its subcellular localization and its ability to participate in the initiation of viral DNA synthesis. These regulatory events will be discussed later in the context of the life cycle.

Polyomavirus small T antigen is found in both the nucleus and the cytoplasm. Small T antigen is a cysteine-rich protein ranging in size from 124 to 198 residues and shares its N-terminus with large T antigen (i.e., those residues encoded

up to the 5' large T antigen splice site) but contains a unique C-terminal region. Small T antigen contains the same N-terminal J domain as large T antigen and a unique C-terminal domain (Fig. 53.4). The unique domain of the mammalian polyomavirus small T antigens contains a highly conserved set of cysteine and histidine residues that bind to two zinc molecules.^{43,44} These zinc-binding domains serve an important role in binding to the cellular protein phosphatase 2A (PP2A).²⁰⁰ PP2A is a trimeric complex consisting of two regulatory subunits A and B that bind to the catalytic C subunit. Small T antigen binds directly to the PP2A A subunit where the B subunit normally binds and thereby displaces or replaces the B subunit. SV40 small T antigen binds specifically to the A α (PPP2R1A) subunit, while MPyV small T antigen binds to both the A α and A β (PPP2R1B) subunits.⁴ The small T antigen–PP2A complex contains also the C α (PPP2CA) or C β (PPP2CB) catalytic subunit. There are at least 18 different B PP2A subunits identified in mammalian cells. At the very least, SV40 small T antigen can displace the B56 α (PPP2R5A), B56 γ (PPP2R5C), and PR72/PR130 (PPP2R3A).²¹⁹ It is likely that the polyomavirus small T antigen–PP2A complex not only serves to disrupt the cellular PP2A complexes but also is likely to retain specific phosphatase activity directed toward substrates. Notably, the bird polyomavirus small T antigens do not contain the conserved cysteine/histidine residues that serve to bind zinc, and it is not known if they are capable of PP2A binding.

The middle T antigen of MPyV shares its N-terminal J domain and PP2A-binding domain with small T antigen (Figs. 53.4 and 53.6). The MPyV middle and small T antigens are identical for the N-terminal 191 residues until a splice junction that removes four nucleotides resulting in an additional 230 residues at the C-terminus of middle T antigen. In contrast, small T antigen contains only four unique amino acids after this intron. The unique middle T antigen C-terminus is encoded by an alternate reading frame used for coding the second exon of large T antigen. Notably, middle T antigen contains an N-terminal J domain in common with both large and small T antigen and, like small T antigen, binds to the A and C subunits of PP2A. The additional MPyV middle T residues mediate binding to several proteins involved in signal transduction, including the SRC tyrosine kinase, the SHC1 phosphotyrosine docking protein, phospholipase C (PLCG1), and phosphatidylinositol 3-kinase (PIK3CA and PIK3R1).²²³ MPyV middle T antigen can also bind to the SRC-related tyrosine kinases YES1 and FYN. The C-terminus of middle T antigen contains

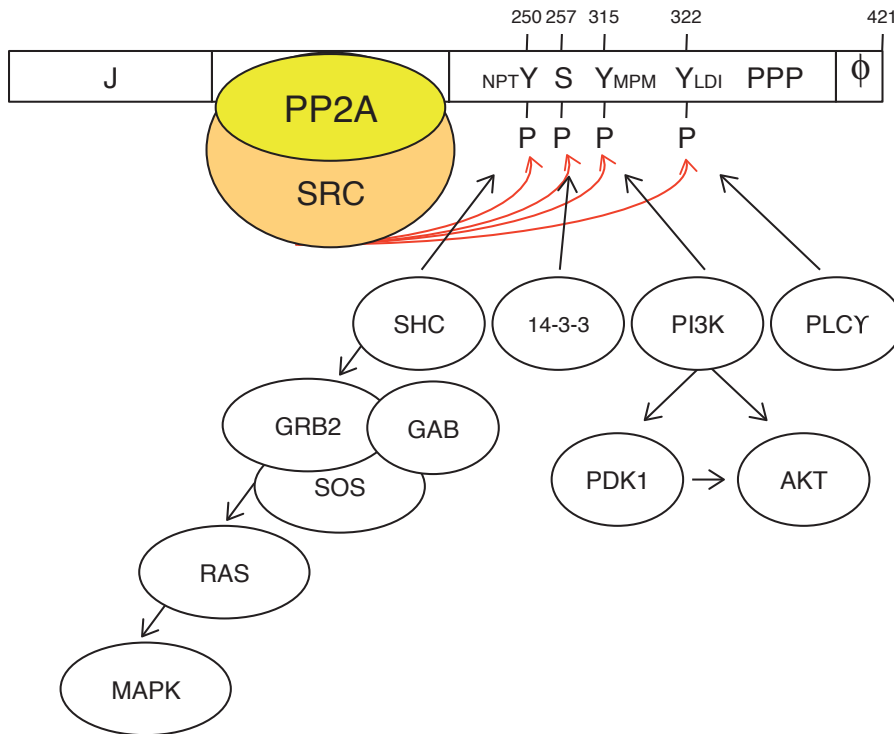

FIGURE 53.6. Mouse polyomavirus (MPyV) middle T antigen assembles an activated signaling complex. Tyrosine residues 250, 315, and 322 are phosphorylated by associated SRC kinase. Residues surrounding the phosphorylated tyrosine residues are required for specific association with SHC, 14-3-3, phosphoinositide 3-kinase (PI3K), and phospholipase C. PPP represents the proline-rich sequence. The C-terminus contains the hydrophobic membrane attachment site. (Adapted from Schaffhausen BS, Roberts TM. Lessons from polyoma middle T antigen on signaling and transformation: a DNA tumor virus contribution to the war on cancer. *Virology* 2009;384[2]:304–316.)

a 22-residue hydrophobic domain that moves the newly translated middle T antigen from the cytoplasm through the endoplasmic reticulum (ER) to the inner plasma membrane.²⁸⁵ The combination of membrane localization with recruitment and activation of several enzymes enables middle T antigen to function as a constitutively activated tyrosine kinase that triggers downstream signaling in the RAS and MEK pathways.

STAGES OF REPLICATION

Mechanism of Attachment

Prior to the 21st century, the identity of the cell surface receptors for polyomaviruses was poorly understood. Early studies on SV40 indicated that it used the major histocompatibility complex (MHC) class I antigens to bind to cells.²⁹ Supporting evidence for this model included observations that antibodies against MHC class I blocked virus binding to rhesus monkey kidney cells and the inability of virus to bind well to human cells that do not express MHC class I in nonexpressing cells restored binding. Although the MHC class I antigens were implicated as the SV40 receptor, they were not sufficient to account for all binding. For example, virus binding occurred only on the apical surface of polarized monkey epithelial cells, while MHC class I antigens were expressed on both the apical and basolateral surfaces. In addition, expression of MHC class I on human kidney epithelial cells was not sufficient for SV40 infection.

Subsequent results challenged the notion that SV40 uses a protein molecule as its receptor, indicating instead that it uses the branched ganglioside, GM1 (Fig. 53.7).²⁶⁵ This finding is more consistent with the route of entry of the virus through endosomes. In these studies, a rat cell line that did not express gangliosides and was unable to be infected by SV40 was ren-

dered susceptible by preincubation with GM1. Gangliosides are glycosphingolipids that combine a sialylated oligosaccharide with ceramide consisting of sphingosine and a fatty acid. The sialic acid is critical for viral binding to the cell. In addition to providing a binding site for the virus, the gangliosides direct the virus to the correct endocytic pathway.²⁰⁹ The efficiency of SV40 infection is dependent on the relative concentration of GM1 on the cell surface as well as its ability to activate focal adhesion kinase (PTK2).²⁴⁴

Other polyomaviruses use different forms of gangliosides as receptors (Fig. 53.7). For example, MPyV uses GT1b or GD1b.^{92,265} After initial binding to the ganglioside, MPyV interacts with $\alpha 4\beta 1$ integrin that may serve as a secondary or cell type-specific receptor for viral entry.³⁵ BKPyV also uses gangliosides to enter the cell, as judged by restoration of infectivity to otherwise resistant cells upon preincubation with GT1a and GD1a.¹⁷¹ These branched gangliosides are found on the renal tubular epithelial cells that BKPyV normally infects. Another report indicated that an N-linked glycoprotein containing sialylated oligosaccharides can also mediate BKPyV binding.⁶⁶ Both the glycolipid and glycoprotein contain sialic acid, consistent with early reports that BKPyV can hemagglutinate human red blood cells and that this activity was neuraminidase sensitive. There are conflicting reports regarding the receptor for MCPyV. Although it has been shown that MCPyV VP1 capsomeres can bind the ganglioside GT1b,⁷² pseudovirions can bind heparin moieties.²²⁵

JCPyV binds to lactoseries tetrasaccharide c(LTSc), a linear sialylated oligosaccharide that differs from the branched forms reported for other polyomaviruses (Fig. 53.7). LTSc is a pentasaccharide with the terminal sialic acid linked by an $\alpha 2,6$ bond to the penultimate galactose.^{194,266} In addition, JCPyV uses the 5HT_{2A} serotonin receptor, perhaps as a cell type-specific receptor, for viral entry.⁶⁹ This receptor is expressed on

FIGURE 53.7. Polyomavirus VP1 interactions with gangliosides. **A:** JC polyomavirus (JCPyV) VP1 binds the branched LSTc attached to a lipid or protein. **B:** Mouse polyomavirus (MPyV) VP1 binds to the sialic acid galactose on GD1a or GT1b. **C:** Simian virus 40 (SV40) VP1 binds galactose and sialic acid residues on both branches of GM1. **D:** BK polyomavirus (BKPv) VP1 binds the disialic acid motif of GD1b or GT1b. **E:** Merkel cell polyomavirus (MCPyV) may interact with the sialic acid on both branches of ganglioside GT1b. glial cells, the major target cell for JCPyV. Antibodies to the 5HT_{2A} receptor and receptor antagonists block JCPyV infection, while expressing the receptor in otherwise noninfectible cells renders them susceptible to infection.

Entry, Intracellular Trafficking, and Uncoating

The polyomaviruses use several pathways to enter into the cell and pass through the endosomes to the ER (Fig. 53.8). The pathway from the endosomal compartment to the ER and from the ER to the nucleus is not well understood. After binding to gangliosides on the cell surface, SV40 and BKPv enter the cell using a pathway involving caveolin. The virus is delivered to a neutral pH organelle called the caveosome by endocytosis and then to the ER, where it could be detected by electron microscopy. Recent work has indicated that SV40 may also traffic through a more traditional endocytic pathway to the ER that does not involve a caveosome.⁷⁰ Evidence also indicates that entry of SV40 into the cell requires engagement of a signal transduction cascade through interactions at the cell surface.⁷⁰

Studies with various inhibitors of intracellular structures and processes have shed some light on how the virus travels

within the cytosol. Molecules that interfere with microtubules and prevent movement of vesicles from the endosome to the ER interfere with SV40 infection.²³⁵ Infection can be blocked by the drug, brefeldin A, which inhibits trafficking between the ER and the Golgi apparatus,¹⁹⁷ and a number of other drugs that interfere with endosome maturation and trafficking to the ER.⁷⁰

The polyomavirus capsid begins to disassemble in the ER. Evidence for this includes the appearance of epitopes on VP2 and VP3 that become accessible for immunostaining.¹⁹⁷ In addition, structural changes to the capsid, including disulfide bond reduction and isomerization mediated by ER-resident protein disulfide isomerases, can be detected biochemically at the point when the virus enters the ER.^{93,172,224,274} Furthermore, transmission EM experiments have detected changes in the morphology of virions that were isolated from the ER.¹²¹ It is thought that this change leads to exposure of hydrophobic surfaces of the VP1 molecule on the capsid that facilitates transport across the ER membrane. This step in trafficking also involves ER chaperone proteins. Similar to SV40, it has been shown that the conformation of the MPyV capsid begins to change in the ER due to the action of ERp29, a member of

FIGURE 53.8. Simian virus 40 (SV40) binds to its receptor (GM1) and induces internalization from the plasma membrane by caveolin-dependent or -independent endocytosis. The virus is transported to early endosomes that mature to form endolysosomes. Acidification is required for SV40 internalization and subsequent transport steps. Virus transport to the endoplasmic reticulum (ER) occurs from the late compartments of the endocytic pathway. (Adapted from Jiang M, Abend JR, Tsai B, et al. Early events during BK virus entry and disassembly. *J Virol* 2009;83[3]:1350–1358.)

the protein disulfide isomerase family.^{172,265} Capsid disassembly in the ER or the cytosol may be required because the viral particle is bigger than the functional capacity of the nuclear pore. Evidence for a multistep disassembly process for SV40 includes the exposure of certain VP2 and VP3 epitopes in the ER, while further disassembly occurs in the cytoplasm at a later time point as evidenced by immunoassay detection of the viral genome.¹⁵⁰ The ER-associated degradation pathway, which functions to target misfolded cellular ER proteins for proteasome-mediated degradation, has also been implicated in polyomavirus disassembly.^{91,96,125}

The question of how the genome gets carried to the nucleus remains to be answered. For SV40, it has been speculated that release from the vesicular compartment might involve VP1, as noted earlier, or VP2, by virtue of its myristoylated N-terminus inserting into the lipid bilayer.¹⁹⁷ An NLS in VP3 may mediate entry through the nuclear pore complex, because mutations in this NLS inhibit entry of the virion into the nucleus but do not affect capsid assembly or the production of new virions.¹⁹¹

JCPyV enters the cell through clathrin-coated pits, as indicated by use of inhibitors of this pathway as well as the demonstration that JCPyV co-localizes with transferrin, which is known to use clathrin-mediated entry into the cell.²⁰⁶ Both microtubules and microfilaments play a role in trafficking of

JCPyV to the nucleus.⁷ As with SV40, binding of JCPyV to its receptor induces a signal transduction cascade required for efficient entry that can be inhibited by genistein, a tyrosine kinase inhibitor.²¹¹ JCPyV appears to signal through the extracellular signal-regulated kinase (ERK) or mitogen-activated protein kinase (MAPK) pathway. Using fluorescently labeled virus-like particles (VLPs), it has been shown that JCPyV particles do not disassemble before they reach the nuclear pore and that the nuclear localization signal of VP1 is required for entry into the nucleus.²¹⁰

Transcription

After the polyomavirus genome enters the nucleus, it serves as a template for transcription by the cellular RNA polymerase II. Once inside the nucleus, the viral genome becomes wrapped in nucleosomes containing histone H1 in addition to the four core histones that are present in the virus particle.²⁷⁰ Within the cell, the SV40 viral genome contains 24 nucleosomes with a nucleosome-free region of 400 base pairs encompassing the NCCR of early and late promoters and origin of replication. This is in contrast to the virion, where all regions of the SV40 genome are covered with nucleosomes devoid of H1. Chromatin immunoprecipitation can detect transcriptionally active chromatin, defined by the presence of RNA polymerase II, as early as 30 minutes postinfection with SV40.¹¹ The chromatin at this time also contains hyperacetylated histone H3 and H4,^{10,182} which have been associated with chromatin undergoing transcription initiation and elongation.

Transcription of polyomavirus genes is governed by *cis*-acting sequences in the regulatory region. The SV40 regulatory region has been the most intensively studied and serves as a paradigm for the other polyomaviruses. Seminal studies involving SV40 include the demonstration that AT-rich sequences designated TATA boxes act to direct RNA polymerase II to the proper initiation site for transcription.¹⁵ The SV40 early promoter also contains a series of GC-rich sequences within the 21–base-pair repeat region.^{73,84} The protein SP1, one of the first eukaryotic transcription factors to be cloned, binds to these sequences.⁶⁷ The SV40 early promoter also contains a duplicated element called the 72–base-pair repeat, which was the first *cis*-acting DNA sequence to be deemed a transcriptional enhancer because it could activate transcription when placed several thousand base pairs distant from the transcription start site.^{104,187} Interestingly, most clinical isolates of SV40 carry only a single copy of the 72–base-pair repeat, and it appears that duplication can be selected during passage in culture.¹⁵⁷

In MPyV, the enhancer element consists of two neighboring enhancers called A and B, alternatively α and β , that can act independently. The activity of the MPyV enhancers is dependent on the cell environment, as viral variants that are selected for growth on differentiated or undifferentiated embryonal carcinoma cells have mutations that map to the enhancers.^{54,180} The MPyV early promoter is regulated by the cellular factors characterized as polyomavirus enhancer A binding proteins (PEA) or RUNX1, CBFB, and ETV4 that are expressed when cells are growth stimulated with serum.^{122,176}

The JCPyV promoter shows a distinct tissue-specific activity that correlates with the sites of acute infection. While normal JCPyV virions can attach and enter many types of cells, its host range is restricted to those cells that have the appropriate DNA-binding proteins.²⁶⁷ The JCPyV early promoter

contains sequences that act as transcriptional promoters. These sequences include the TATA box as well as binding sites for the transcription factors SP1, YB1 (YBX1), Pur α (PURA), AP-1, a heterodimer of JUN and FOS, nuclear factor 1 (NFAT), and NF1X. A nuclear factor- κ B (NF- κ B) binding site that includes the NFAT site has been shown to be active for late transcription and possible positioning of other DNA-binding proteins to initiate efficient transcription.⁸⁶ NFAT consists of a family of proteins that are expressed in many cells but have multiple classes with tissue-specific expression. The NF-1 class X (NF1X) is highly expressed in human glial cells, stromal cells, B lymphocytes, and CD34+ stem cells that have all been reported to support JCPyV transcription and replication.⁷⁹ Interactions between YB1 and PURA may also provide cell-specific regulation.⁸⁶

The transcription factors that govern kidney tissue-specific activity of the BKPyV early promoter are not known. While numerous candidate transcription factor binding sites have been identified,¹⁸⁵ it remains unclear which of those factors bind the BKPyV regulatory region in an infected kidney cell.

Rearrangements in the NCCR have also been found in BKPyV and JCPyV.^{30,124,214} Viral regulatory regions referred to as archetype are thought to be associated with naturally circulating polyomaviruses, while rearranged regulatory regions arise when high levels of viral replication occur in culture or during disease. For example, JCPyV early promoter undergoes duplication in virus isolated from patients with PML. These rearrangements may serve to allow higher levels of large T antigen expression and viral replication that are tolerated by the patient's immunocompromised state.⁹⁸ Notably, the δ SV40/JCV hybrid virus contains JCPyV T' antigen and VP1, VP2, and VP3 coding sequences but a hybrid regulatory region with elements of the SV40 enhancer. This laboratory-generated hybrid virus grows with faster kinetics and to higher titers than wild-type JCPyV and has an expanded host range to human and monkey kidney cells as well as monkey glial cells.²⁶⁷

The SV40 early promoter undergoes negative feedback regulation by large T antigen.²⁵⁹ When cells are infected with a temperature-sensitive large T antigen mutant of SV40 at the nonpermissive or restrictive temperature, early mRNAs are overproduced. The ability to repress early transcription is dependent on the binding of large T antigen to the promoter. Mutations that disrupt the DNA-binding domain of large T antigen also typically lead to higher levels of large T antigen.¹³³ Three binding sites, referred to as sites I, II, and III, in the regulatory region are all involved in repression by large T antigen. Because site III overlaps the early promoter elements, it is possible that large T antigen binding acts to prevent binding or displace other transcription factors to that region. Early transcription of MPyV is also regulated by large T antigen, but to a lesser degree and in a DNA binding site-independent manner.

Early gene expression in SV40 is down-regulated by miRNAs encoded by the late transcript.²⁵³ The other primate polyomaviruses have similar sequences that are predicted to be able to form the characteristic hairpin structure of miRNA.²²⁸ Somewhat surprisingly, an SV40 mutant virus lacking the miRNA does not produce more virus than wild type in cultured monkey kidney cells. However, cells infected with the mutant virus are more sensitive to killing by cytotoxic T lymphocytes *in vitro*. This observation led to the proposal that the miRNA serves to limit production of antigens recognized by

the immune system and thereby protecting the infected cell.²⁵³ A mutant MPyV that cannot express its miRNA shows no difference in pathogenesis in animals.²⁵⁴ Therefore, the role of the miRNAs during infection remains to be fully elucidated.

Similar to the early promoter, the late promoter elements span the regulatory region and have been defined in a variety of *in vivo* and *in vitro* systems. In SV40, maximal late transcription requires sequences in the 21-base-pair GC repeats and the 72-base-pair enhancers. Late gene transcription occurs concomitantly with the onset of DNA replication, although replication is not required for activation of late transcription. Large T antigen can promote viral replication as well as late gene expression. Large T antigen can stimulate late transcription, although large T antigen binding the origin of replication is not required for this activity. Rather, transcription activation is accomplished through large T antigen interactions with components of the basal transcription machinery such as TATA-binding protein, a component of TFIID and TBP-associated factor 1 (TAF1), as well as transcription factors late SV40 factor (LSF, TFPCP2), TEF-1 (TEAD1), and SP1. These interactions increase the binding of TBP and another basal transcription factor, TFIIA, to the TATA element.⁵³

The control of late gene expression in MPyV is more complicated. Host range or hr-t mutants that do not express functional small or middle T antigen produce equivalent amounts of late proteins, as does wild-type virus.⁸⁷ However, infection with a virus containing similar mutations in cells with a different genetic background demonstrated a stimulatory role of the two T antigens during the late phase. This does not appear to be solely due to an indirect effect because of amplification of the genome, but also involves a direct stimulation of transcription because the RNA/DNA ratio increases.⁴⁰ These same studies also indicated a role for middle and small T antigens in the induction of early gene expression. As these two T antigens induce signaling pathways that lead to activation of transcription factors known to bind the polyomavirus enhancer, this effect is not surprising. The murine virus also differs from its primate counterparts in how its late primary RNA transcript is processed. The MPyV late poly(A) site is a relatively weak site, resulting in the RNA polymerase circling the viral genome multiple times.^{1,161} The first exon of the late transcript can therefore be spliced to itself multiple times, although the protein-coding sequence is only present once on each mature mRNA.

Translation

Limited studies have been performed to address perturbations in translation by the polyomaviruses. One important question in the polyomavirus life cycle is, how does translation of VP3 occur when the same reading frame on the late transcript encodes both VP2 and VP3? VP3 uses an AUG sequence downstream of the VP2 start codon. Mutagenesis of the SV40 late region between the VP2 and VP3 start codons revealed evidence for two internal ribosome entry sites (IRESs) that could potentially promote cap-independent translation of VP3.²⁷⁹ This observation may be particularly important because SV40 infection leads to a decrease in cap-dependent translation.²⁸⁰ SV40 small T antigen leads to decreased phosphorylation of 4E-BP1 that in turn binds to and represses eIF4E, reducing cap-dependent translation. This inhibitory effect on phosphorylation 4E-BP1 required the SV40 small T antigen PP2A binding domain and was most evident at late times after infection.

The ability of SV40 small T antigen to reduce levels of 4E-BP1 phosphorylation during infection contrasts with the effects of MCPyV small T antigen constitutively expressed in Merkel cell carcinoma. As described later, part of the MCPyV genome is randomly integrated into the host cell chromosomes in a manner that permits expression of small T antigen and the N-terminal half of large T antigen.⁷⁸ In cell lines derived from Merkel cell carcinoma that express MCPyV small T antigen, downstream targets of AKT and mTOR including 4E-BP1 were hyperphosphorylated, leading to increased cap-dependent translation.²³⁸ This activity appeared to contribute to the transforming activity of MCPyV small T antigen because a phosphorylation-resistant form of 4E-BP1 reduced cell growth in the Merkel cell carcinoma cell lines. Notably, this activity was independent of its PP2A-binding domain, suggesting the possibility that this represents a function unique to MCPyV small T antigen.

Replication of Viral Genomic DNA

To a great extent, polyomavirus large T antigen orchestrates the viral life cycle. Studies of SV40 large T antigen led to groundbreaking insights into eukaryotic DNA replication including the role of its DNA-binding and helicase activities, culminating in the establishment of the first *in vitro* system for eukaryotic DNA replication. The history of these seminal discoveries and the scientists who made them is well described in a recent review.⁷⁵ While many of the insights into the molecular functions of polyomavirus large T antigen have come from studies on SV40, investigations into other polyomaviruses have also made substantial contributions to our understanding of viral replication.

The large T antigen binds directly to the viral origin of replication and functions as a helicase to unwind the viral dsDNA to enable replication. Large T antigen also serves to recruit cellular proteins including replication protein A (RPA), DNA polymerase/primase, and topoisomerases I and II to facilitate viral genome replication. In addition, large T antigen induces changes in the cell to facilitate viral replication including the formation of viral replication centers or foci within the nucleus.

Polyomaviruses normally infect quiescent or growth-arrested cells that are not actively proliferating, yet they require the host cell's DNA synthetic machinery that is fully active during the S phase of the cell cycle. Large T antigen plays a role in inducing exit from the quiescent state and entry into S phase. Large T antigen also functions to counter the cell's apoptotic responses induced by viral DNA replication. The cellular DNA damage response to replicating viral genomes is also triggered by large T antigen and appears to be required for efficient viral replication.

The SV40 origin of replication contains three regions, a core origin of 64 base pairs with four pentanucleotide (GAGGC) sequences organized as a pair of inverted repeats flanked by an early palindrome (EP) on the early side and an A/T-rich region on the late side (Fig. 53.9).²⁴² The large T antigen DNA-binding domain binds directly to the pentanucleotide sequence.¹⁷⁹ After two molecules of large T antigen bind to opposing inverted pentanucleotide sequences, they each recruit five additional molecules of large T antigen to form a hexamer. The two hexamers face each other in a head-to-head orientation that surrounds the origin. After double-hexamer formation, large T antigen initiates melting of the DNA in the EP region and untwisting of the A/T region. Viral DNA is opened to form single-stranded DNA (ssDNA) followed by large T antigen–recruiting RPA and topoisomerase I. The helicase domain of large T antigen recruits the DNA polymerase α /primase complex (POLA1, POLA2, PRIM1, PRIM2) that contributes to RNA Okazaki primer formation on the lagging strand (Fig. 53.5).

Besides its role in initiation of DNA synthesis, large T antigen is also required for elongation of the growing chains. Elongation is carried out by DNA polymerase δ (POLD1, POLD2, POLD3, POLD4) in conjunction with its accessory factors, proliferating cell nuclear antigen (PCNA) and replication factor C (RF-C). Large T antigen has an ATPase-dependent 3' to 5' helicase that advances each hexamer in opposite orientations along the viral DNA. Replication occurs in a bidirectional manner and ends with the de-catenation of the two linked circular molecules by topoisomerase II.

The bidirectional nature of SV40 DNA synthesis was demonstrated in two ways. First, Danna and Nathans⁵⁶ performed an elegant experiment in which they pulse-labeled infected cells with ³H-thymidine for 5 to 15 minutes, isolated fully replicated DNA molecules, and determined what parts of the genome were labeled. The theory behind this approach is that the labeled thymidine would appear farthest from the origin of replication in cells that were labeled for the shortest time periods, because those were the closest to completion, and extend back toward the origin as the labeling time was extended. This allowed the mapping of the origin as well as the determination that replication was bidirectional. The second approach used shadowing of DNA with electron microscopy imaging of replicating SV40 and MPyV.²⁷¹ Here, replication forks were visualized and mapped in relation to the ends of the DNA molecules, which had been digested with a restriction endonuclease at a unique site on the chromosome.^{48,76,102}

Examination of the crystal structure of the large T antigen helicase domain when bound to adenosine triphosphate (ATP) or adenosine diphosphate (ADP) led to the proposal that ATP

FIGURE 53.9. The minimal simian virus 40 (SV40) origin of 64 base pairs contains a central perfect palindrome with four pentanucleotides (P) GAGGC, the early palindrome (EP), and AT-rich region. The large T antigen DNA-binding domain binds to the pentanucleotide sequence. A second large T antigen binds to another pentanucleotide sequence on the opposite strand. Each large T antigen forms a hexamer leading to a double hexamer in a head-to-head orientation surrounding the origin. Adenosine triphosphate (ATP) hydrolysis by the hexamer leads to melting of the AT-rich and unwinding of the EP regions.

hydrolysis induces conformational changes that cause twisting of the hexamers resulting in expansion and constriction of the central channel that resembles the movement of an iris within an eye.¹⁶³ This could explain how large T antigen generates the motive force that is necessary to move DNA for replication. It should be emphasized that although many of the steps involved in polyomavirus DNA replication and many cellular factors that contribute to this process have been identified, there are many important questions to be resolved. In particular, it is not known where the formation of the ssDNA intermediates occurs relative to large T antigen, how it passes through the large T antigen hexamer, and how the DNA moves through the double hexamers to enable bidirectional DNA synthesis.

Phosphorylation of large T antigen regulates its ability to drive DNA synthesis.²⁴² In SV40, phosphorylation of large T antigen threonine residue 124 by cyclin-dependent kinases enhances binding of the protein to the origin of replication and subsequent unwinding.^{178,184} In MPyV, the corresponding large T antigen threonine residue 278 is also phosphorylated, and mutation of this residue abolishes replication function. Conversely, phosphorylation of SV40 large T antigen serine residues 120 and 123 inhibits replication.³⁷ The serine residues can be phosphorylated by casein kinase I and dephosphorylated by PP2A.

The N-terminal J domain of large T antigen contributes to viral DNA replication, functioning through binding to HSC70. While the J domain is not required for viral DNA replication *in vitro*, it plays a significant role *in vivo*.³¹ Notably, the J domain from the human HSP40 homolog HSJ-1 protein can support SV40 DNA replication when it was substituted for the homologous domain of large T antigen, suggesting that interaction of large T antigen with HSC70 and the host cell heat shock system facilitates viral replication. The mechanism by which the large T antigen J domain stimulates DNA replication is not known, but may involve chaperone-mediated rearrangements of the initiation complex on the DNA.

An essential contribution of large T antigen to viral replication is to induce the cell to enter the cell cycle. Although polyomaviruses normally infect cells that are not actively dividing, they require the host cell's DNA synthetic machinery, produced and activated during S phase, for replication of the viral genome. Large T antigen drives the resting cell into S phase by binding to pRb (RB1), the product of the retinoblastoma susceptibility gene, and the Rb-related proteins p107 (RBL1) and p130 (RBL2).⁵⁹ The Rb tumor suppressor proteins, sometimes referred to as pocket proteins, prevent entry of the cell into S phase through binding and repression of the E2F family of transcription factors.⁶² During the quiescent (G0) and G1 phase of the cell cycle, pRb and p130 form complexes with E2F on the promoters of genes required for DNA synthesis. Notably, p130 binds to the repressor E2F4/DP1 heterodimer and recruits a five-protein complex to the promoters of more than 800 E2F-dependent, cell cycle-regulated genes.¹⁶⁹ The DREAM (DP1, RBL2, E2F4, and MuvB) complex is disrupted when large T antigen binds to p130, thereby releasing the MuvB core complex and enabling activation of E2F-dependent genes. When a cell is induced to divide physiologically, cyclin-dependent kinases serve to phosphorylate the Rb family proteins, enabling their release from E2F and thereby permitting gene expression. Large T antigen subverts this pathway by binding to Rb family proteins and disrupting their binding to E2F. The LXCXE

motif in large T antigen binds directly to the Rb proteins.¹⁴⁵ In addition, the large T antigen N-terminal J domain cooperates with the LXCXE motif binding of Rb family proteins to facilitate their release from E2F. The SV40 large T antigen J domain also perturbs the phosphorylation status and stability of Rb-related proteins, thereby contributing to loss of their E2F repression functions.^{251,252}

In addition to causing the cell to enter S phase, SV40 large T antigen carries out another important role in establishing the proper cellular environment for replication. The inappropriate entry into S phase induced by large T antigen causes the cell to activate a p53-dependent growth arrest and proapoptotic response. The p53 tumor suppressor protein was first discovered by virtue of its being co-immunoprecipitated with SV40 large T antigen from cellular protein extracts.^{153,168} Large T antigen binds directly to the DNA-binding domain of p53, thereby disrupting p53's ability to transactivate its target genes such as *p21* (*CDKN1A*), *PUMA*, and *MDM2* involved in cell cycle arrest, apoptosis, and autoregulation, respectively.

The ability of large T antigen to activate p53 is due to expression of ARF (alternate reading frame), a product of the *CDKN2A* gene that also expresses the CDK4 inhibitor p16-INK4A. ARF functions to stabilize p53 by binding to and inhibiting the E3 ubiquitin ligase activity of MDM2 directed toward p53. Although normal cell cycle entry does not induce ARF expression, SV40 large T and MPyV middle T antigens induce expression of ARF. Although many polyomavirus large T antigens can bind to p53 and thereby inactivate its growth inhibitory and apoptotic response, MPyV large T antigen is notable for its inability to bind directly to p53. Nonetheless, MPyV is able to counter the p53-mediated growth arrest by large T antigen inactivation of the pRb family proteins⁶³ and by small T antigen inhibition of ARF.¹⁸⁸

Recent evidence indicates that the cellular DNA damage response (DDR) is required for SV40 replication.²⁸² SV40 infection induces a cellular DDR response that includes activation of the ATM kinase, resulting in phosphorylation of the specialized histone γ -H2AX and the checkpoint kinase CHK2. Large T antigen co-localizes with phosphorylated ATM and γ -H2AX on DNA to form nuclear foci that include the MRN complex (Mre11, Rad50, and Nbs1) and 53BP1. Large T antigen alone without viral DNA can induce the DDR, and this may be dependent on large T antigen interaction with BUB1.¹¹¹ In addition to the DDR, much attention has been focused recently on the role of nuclear structures called promyelocytic leukemia nuclear bodies (PML-NB) during replication and infection.²⁷ In BKPyV infection, large T antigen co-localizes with PML-NB at very early times and, concomitant with the onset of viral DNA replication, induces a dramatic reorganization of PML-NB.¹²⁶ It remains unclear if the DDR and changes in the PML-NB are a consequence or a requirement of viral replication.

Assembly

Assembly of polyomaviruses begins with the translocation of VP1, VP2, and VP3 into the nucleus and the formation of capsomeres. The VP1, VP2, and VP3 from SV40 and MPyV each contain nuclear localization sequences. VP2 and VP3, in the absence of VP1, do not accumulate in the nucleus but rather require VP1 for nuclear transport, indicating that these

proteins may be imported as a complex. The VP2 or VP3 NLS may be more important for trafficking of incoming virus from the ER to the nucleus than for import of the newly synthesized proteins during the late phase of the infection. This model fits with the data indicating that VP2 and VP3 become exposed as the virus transits through the ER.

Capsomeres assemble into viral particles and DNA is incorporated into the virion. It is unclear whether empty capsids are precursors to mature, DNA-containing virions or dead-end products. While it has been reported that a *cis*-acting sequence in the origin region of SV40, *ses*, enhances DNA packaging,⁵² DNA molecules that lack this sequence element can still be encapsidated.

Purified recombinant VP1, expressed in bacteria, yeast, or baculovirus-infected insect cells, can self-assemble into capsomeres. Under appropriate conditions, these capsomeres form capsid structures referred to as VLPs. Therefore, viral DNA, VP2, and VP3 are not required for capsid formation. Changes in ionic strength and pH of the buffer can lead to formation of other structures including tubular moieties and T = 1 icosahedrons. It has been shown that chaperones such as HSP70 are required for efficient capsid assembly. VLPs are very similar to authentic virions and have been used for basic studies on receptor binding, virus entry, intracellular trafficking, and the immune response. VLPs have also been investigated as vehicles for delivery of genes and small molecules^{38,88,258} and have been extensively used for serologic assessment of polyomavirus infection.^{34,273}

Release

The manner by which polyomaviruses leave the cell is poorly understood. While some studies indicate that the virus causes lysis of the cell, others indicate that virus can be shed from intact cells. For example, SV40 infection can cause a cytopathic effect (CPE) or vacuolating effect with destruction of the cell. Alternatively, SV40 can leave polarized epithelial cells from the apical surface and can exit nonpolarized epithelial cells without killing them.⁴⁵ A regulated virus exit process is suggested by the observation that SV40 can be detected in cytoplasmic membrane vesicles using electron microscopy, and release of virions is inhibited by monensin, which blocks vesicular transport. Alternatively, SV40 VP4, translated from the VP1 mRNA using an internal methionine codon in the VP1 open reading frame, may function as a viroporin that disrupts membranes to promote virus release.²¹²

JCPyV causes cell death through lytic infection of glial cells. Infection of astrocytes cultured *in vitro* supports a progressive JCPyV infection that leads to necrotic cell death and virion release.²²⁹ Notably, this model system did not yield any evidence for apoptosis by JCPyV infection.

The agnoprotein may also contribute to assembly and egress. SV40 isolates containing mutations in agnoprotein replicate with wild-type kinetics but produce plaques that are smaller than wild type due to inefficient release of mature virions from the cell. Other phenotypes of agnoprotein mutants that could account for inefficient viral replication include improper localization of VP1. At the nuclear envelope, agnoprotein has been shown to dissociate heterochromatin protein 1 (HP1) from the lamin B receptor, resulting in destabilization of the envelope, perhaps explaining how agnoprotein could facilitate egress.¹⁹⁸ While some of the large T antigen host range

mutations affect agnoprotein expression, the assembly defect in these mutants cannot be complemented by expression of agnoprotein *in trans*.²⁴⁵ Additional functions have been proposed for the JCPyV agnoprotein, including as a viroporin on the nuclear membrane.¹⁴²

PATHOGENESIS AND PATHOLOGY

The principal target cell for initial entry of polyomaviruses has been difficult to identify. It appears that once exposed to a polyomavirus, an individual maintains a lifelong persistent infection present in a variety of tissues. Therefore, it can be difficult to distinguish the site of initial entry from a site that acts as a reservoir for lifelong infection. While many studies have found the presence of polyomaviruses in a variety of tissues from immunocompromised patients, there is scattered evidence that these tissues may represent reservoirs for virus in normal immune competent individuals as well. For example, many polyomaviruses including SV40, BKPyV, and JCPyV are present in the kidney and excreted in the urine. Exposure to infected urine could be a source of infection for these polyomaviruses. There have been reports of JCPyV infection in human colonic epithelial cells and isolation of BKPyV and JCPyV from stool specimens.²³ Notably, BKPyV, JCPyV, MCPyV, KIPyV, and WUPyV have been frequently detected in sewage samples,²⁵ while BPpyV has been detected in farm wastewater samples.¹¹⁹

JCPyV is able to productively infect tonsillar stromal cells in culture with efficiency nearly comparable to human glial cells. JCPyV DNA has also been found in lymphoid tissues including bone marrow and spleen.¹¹⁷ JCPyV DNA has been identified in tonsil stromal cells and in B cells isolated from tonsils.¹⁸⁶ The ability of JCPyV to infect tonsillar stromal cells in culture and the presence of JCPyV DNA in tonsil tissue suggest the possibility that the initial infection can occur in this tissue.

BKPyV has been detected in lung tissue from one case of interstitial pneumonia in a hematopoietic stem cell transplant patient and in the respiratory tract and tonsil tissue in another,^{100,221} as well as in salivary glands.¹²³ This, together with the observation that the majority of the population in both developed and underdeveloped regions of the world seroconverts in early to midchildhood, suggests a respiratory route of transmission.

WUPyV and KIPyV can be detected in respiratory secretions that represent either the site of acute infection or latency. For example, WUPyV was frequently detected in tonsils and nasopharyngeal lymphoid tissue from immunocompetent children.⁴⁷ WUPyV and KIPyV were also found in plasma, urine, and respiratory samples of renal transplant patients.⁴⁹

For some polyomaviruses, there is evidence for maternal-fetal transmission. MPyV can be acquired vertically through transplacental transmission or direct contact as neonates.²⁸¹ BKPyV has also been reported to undergo *in utero* and transplacental transmission.²⁸ In contrast, a recent study determined that the human polyomaviruses WUPyV, KIPyV, and MCPyV were not present in more than 500 fetal tissues, although serologic assessment indicated that nearly half of the mothers had been infected with MCPyV.²²⁰

Polyomavirus infection in birds spreads quickly in susceptible flocks. Avian polyomaviruses can be found in the urine and

fecal matter in flocks, suggesting an oral route of transmission. A recent report demonstrated upward vertical transmission for APyV by blowfly larvae present in nests.²⁰⁷ Bird fledglings become viremic after being bitten by the larvae and shed virus from their cloaca, thereby infecting the breeding adults. In parrots, viremia was followed by cloacal shedding within 1 week of experimental infection.²⁰⁵ Infected birds may harbor virus persistently throughout life, but acute infection can cause neurologic damage and death in younger birds.²⁴⁸

Immune Response

Humoral immune responses that are immunoglobulin G (IgG) or IgM occur in all animal species infected with polyomaviruses and show some cross-reactivity within rodent, primate, or avian families but not across those barriers unless immunized with laboratory-made virions or proteins. Antibody against polyomavirus is IgG, although a number of reports identified an IgM response with onset of clinical symptoms of infection.^{80,81} IgM and IgA antibodies have been detected against BKPyV in bone marrow and renal transplant patients.⁶⁴ The Multicenter AIDS Cohort Study found that approximately 80% of all participants had immunoglobulin titers specific for MCPyV VP1. Within the remaining group of seronegative participants, approximately 26% seroconverted in the following 4 years. Notably, no clinical signs or symptoms associated with acute MCPyV infection and subsequent seroconversion were appreciated.²⁶¹

Measurements of cellular immune responses to JCPyV and BKPyV in infected individuals have identified CD8+ cytotoxic T lymphocytes (CTLs) that recognize epitopes on VP1 and large T antigen. The epitope on BKPyV VP1 amino acid residues 108 to 116 elicits a T-lymphocyte response that also recognizes JCPyV epitope VP1 p100.¹⁴⁹ Using tetramer assays or CTL cell lysing assays, CD8+ T cells can be found in the peripheral circulation that are human leukocyte antigen (HLA) restricted to genotype A*02, present in a large proportion of the population.⁶⁵ Viral-specific CD8+ T lymphocytes show a good correlation with time of survival in PML patients and could be useful as a prognostic indicator of disease progression.¹⁴⁷

A CD8+ cytotoxic T-cell response was noted in an analysis of mRNA expression profiling of Merkel cell carcinoma.²⁰⁴ Notably, patients with a better prognosis had a statistically significant increase in genes related to the CD8+ response. The response was most likely due to infiltrating CD8+ cells that were captured when the mRNA was prepared from the tumor.

There is also a T-cell-mediated immune response in SV40-infected monkeys and MPyV-infected mice that confers protection from infection and is thought to play a role in establishing viral persistence in SV40- and MPyV-infected animals. Stimulation of CD8+ CTLs in mice, however, affects different pathways involving CD28 and CD40 ligands during the course of either acute or persistent infection.¹⁴⁰

Persistence

One of the interesting biological characteristics of all the polyomaviruses is the maintenance of a chronic and lifelong viral infection in their hosts. Usually viral persistence is established in the kidney as judged by viral excretion in the urine that can show remarkably high levels of virus release ranging from 10^3 to 10^8 viral copies per milliliter. Virus can be found in uroepithelial cells and in ductal pathways. However, there is no apparent pathology associated with such high levels of urinary excretion

unless there is an underlying immune-compromised condition. There is no information, however, on the mechanisms of viral persistence, what triggers viral synthesis and multiplication, and the consequences of lifelong virus shedding in the urine. There is no evidence that polyomaviruses enter a true latent state in which there is little or no viral gene expression or genome replication as with the herpes family of viruses.

For the human polyomaviruses, the kidney or urothelium is the primary location for BKPyV, whereas the kidney and lymphoid organs are locations for JCPyV with differing consequences of infection. The sites of persistence for WUPyV and KIPyV have not been determined, although viral DNA has been recovered from respiratory secretions. MCPyV, HPyV6, and HPyV7 can be isolated from normal skin.²²⁶ MCPyV was shed as virions from the skin. Given the rarity of Merkel cells in skin, this raises the possibility that MCPyV is produced by the stratified epidermal keratinocytes rather than less abundant Merkel cells.

Transformation

Since their initial discovery, polyomaviruses have been used to study the transformation of normal cells. The initial observations of the tumor-causing ability by MPyV followed by the observation that injection of SV40 into newborn hamsters caused tumors heralded the potent transforming activities of polyomaviruses. Since then, many more polyomaviruses have been identified and their transforming activity has been compared to MPyV and SV40. The transforming activity of the polyomaviruses is limited to the T antigens. The VP coat proteins or agnoprotein does not have transforming activity. The large and small T antigens of most mammalian polyomaviruses as well as middle T antigen of MPyV and HaPyV have transforming activities. Large T antigen transforms cells in part by binding to and inactivating the Rb and p53 tumor suppressor proteins. The contribution of small T antigen to transformation is dependent in part on binding to the protein phosphatase PP2A. Middle T antigen has unique transforming activities related to its ability to assemble an activated, tyrosine kinase signaling complex.

The study of cellular transformation and its relationship to tumorigenesis was led by seminal studies of the polyomaviruses. Early studies on transformation included colony or focus formation studies of primary mouse embryo fibroblasts or established 3T3 cells. Using SV40, Risser and Pollack²¹⁵ described a hierarchy of the transformed phenotype that began with immortalization of primary cells, followed by their growth in reduced serum conditions, anchorage-independent growth, and ultimately formation of xenograft tumors in mice. The degree of transformation was dependent in part on the level of large T antigen expression; the higher level of large T antigen expressed enabled the complete transformed phenotype.

The polyomaviruses have been used to study transformation and oncogenesis in a variety of ways. In addition to using the whole virus genome, expression vectors for the T antigens has been used to study transformation. Mammalian expression vectors that drive the expression of the early region containing large and small T antigen or complementary DNAs (cDNAs) specific for large T antigen have been used in cells as well as in transgenic mice.

A seminal breakthrough in the study of human carcinogenesis was made when it was demonstrated that the combination

of only four genetic elements could fully transform normal human cells. Expression of the SV40 large T and small T antigens, an activated form of HRAS, and the catalytic subunit of human telomerase reverse transcriptase (TERT) could completely transform normal human cells, including the ability to form tumors as a xenograft in an animal.^{108,109} This strategy has been used to transform a wide variety of human cell types including astrocytes, myoblasts, and epithelial cells from lung, breast, and prostate tissues.¹⁴¹ In addition, substitution of SV40 large and small T antigen with human oncogenes and tumor suppressor genes led to the establishment of a model system of human oncogenesis composed of completely human genetic elements.⁴¹ This approach has been expanded in high-throughput screens of cDNAs for gain-of-function and short hairpin RNA interference (shRNAi) molecules for loss of function to identify novel oncogenes and tumor suppressor genes, respectively.

The transforming activity of polyomaviruses is balanced by its capacity to lyse cells during infection. Polyomaviruses can transform cells and form tumors under circumstances when the T antigens are expressed but the virus does not undergo replication at sufficiently high levels to cause lysis of the cell. If the infected cell is permissive for virus replication, then it will undergo lysis and not undergo transformation. Conversely, if a cell is restrictive for replication but enables T antigen expression, then it may undergo transformation. Typically, a restrictive cell undergoes transformation when the polyomavirus DNA becomes integrated into the host chromosomal DNA in a way that sustains expression of the T antigens. This situation occurs when MCPyV DNA becomes integrated into the host genome and contributes to the development of Merkel cell carcinoma. Alternatively, a cell can be semipermissive and sustain low levels of viral replication while expressing sufficient levels of T antigens to change the cellular growth characteristics.

The nonpermissive or restrictive environment is generally caused by species-specific differences in DNA replication factors. The best understood of these is the interaction of large T antigen with the DNA replication machinery. Large T antigen binds to the DNA polymerase α /primase complex and recruits it to the viral origin of replication. SV40 cannot replicate its DNA in rodent cells, at least in part due to its inability to bind the DNA polymerase α /primase in these cells.

Another level of permissiveness involves the interaction between large T antigen and p53. Just as the large T antigen can affect p53 function, p53 has reciprocal effects on the ability of large T antigen to function as a replication factor.⁸³ A tissue-specific example of this restriction is found in the differential ability of SV40 to replicate in human fibroblasts and mesothelial cells.²² In fibroblasts, the virus replicates quite efficiently, whereas replication is severely limited in mesothelial cells. The latter cells have higher steady-state levels of p53 than the former, and decreasing p53 expression in mesothelial cells with antisense strategies increases viral replication. Changes in the regulatory region of the virus can also change the outcome of the infection from lytic to nonlytic. Monkey kidney cells transduced with a viral genome containing a deletion of the SV40 origin of replication that disables replication are readily transformed.⁹⁵ Rearrangements in the BKPyV NCCR that cause a decrease in DNA replication also enhance the transforming ability of the virus.²⁷⁵

A wide variety of transgenic mice lines have been generated that express polyomavirus early region or individual T antigens. Many of these animals develop tumors dependent on the specific promoter used. For example, transgenic mice expressing the SV40 early region have led to the TRAMP mouse model of prostate cancer and the rat insulin promoter (RIP)-Tag model for pancreatic neuroendocrine tumors. MPyV middle T antigen transgenic mice have been developed using a variety of promoters. Mice with middle T antigen expression driven by the mouse mammary tumor virus long terminal repeat (MMTV-LTR) develop multifocal mammary adenocarcinomas that can become metastatic to the lung in 3 months.¹⁰⁶ Several different strains of mice expressing MPyV middle T antigen in the prostate tissues have been developed. Mice with middle T antigen driven by the C3 promoter develop mouse prostatic intraepithelial neoplasia (mPIN).²⁶⁰ Another strain using the (ARR)2-Probasin promoter develop mPIN as early as 8 weeks of age that develops over time to become invasive cancer.¹⁵⁹

BKPyV induces different types of tumors dependent upon the rodent species and route of inoculation. Intracerebral inoculation of BKPyV in hamsters results in ependymomas, neuroblastomas, and pineal gland tumors. Intravenous inoculation causes pancreatic islet cell tumors, fibrosarcomas, and osteosarcomas. Mouse inoculations frequently result in fibrosarcomas, liposarcomas, nephroblastomas, gliomas, and choroid plexus tumors that are also common in SV40 T protein-expressing transgenic mice.¹⁹² BKPyV tumor induction shows some viral strain variation, with the prototype isolate, BKPyV Gardner, possessing the greatest oncogenic potential. It is unclear whether *trans*- or *cis*-acting factors influence tumor formation frequency, but it is assumed that the regulatory sequence variations have a dominant role.

JCPyV inoculation into hamsters also results in multiple tumor types including medulloblastomas, glioblastomas, and pineocytomas. However, unlike BKPyV or SV40, JCPyV induces a grade 4 glioblastoma multiforme or malignant astrocytoma upon intracranial inoculation into owl and squirrel New World monkeys. In contrast, JCPyV does not induce tumors when inoculated into Old World macaques or rhesus or African green monkeys. Malignant brain tumors induced by JCPyV inoculation revealed that the viral genome was integrated into the cellular DNA.¹⁸³ The astrocytoma cells can be explanted and grown in culture. In some tumor cell explants, JCPyV large T antigen expression gradually diminishes upon continuous culture and it enters into senescence. One owl monkey tumor, however, demonstrated unique properties, not only surviving in culture but also becoming transplantable back into other owl monkeys. JCPyV DNA in these tumor cells, termed 586, was both integrated in the cell chromosome and episomal in high copy number. JCPyV infectious virus was produced continually in culture, resulting in a persistent viral or carrier culture.¹⁷⁵

EPIDEMIOLOGY

Members of the family *Polyomaviridae* are found throughout the world in bird, rodent, nonhuman primate, and human populations. The presence of polyomaviruses in the human population has been extensively studied. In one approach, evidence for prior infection by individual polyomaviruses has been performed with serum collected from individuals. For the most

part, sera testing with viral particles or more recently using VLPs prepared from recombinant VP1 corresponding to the different polyomaviruses enables determination of prior exposure. These serologic studies have revealed that infection with polyomavirus occurs as early as several months of age and increases in frequency until, by adulthood, most types of polyomaviruses have infected nearly all individuals. In the second approach, sequencing of polyomavirus DNA collected from the urine or the skin enabled determination of the presence of the unique strain of polyomaviruses. This approach has revealed that for the most part, an individual maintains a lifelong infection with polyomavirus. Although protective immunity against individual polyomaviruses may prevent reinfection, it may not be sufficient to prevent infection with a different strain of the same polyomavirus. In addition, these studies have revealed that polyomaviruses have co-evolved along with the human population.

Evidence for prior infection with specific polyomaviruses can be determined in a sensitive enzyme-linked immunosorbent assay (ELISA). Recombinant forms of VP1 from the corresponding polyomavirus are produced in bacteria or insect cells and spontaneously form VLPs. The purified VLPs are adhered to a plate and used to capture specific immunoglobulin molecules from sera. The relative amount of antibody captured is detected using anti-IgG- or anti-IgM-labeled secondary antibodies. In a useful variation of this assay, the recombinant VLP from a polyomavirus can be used to deplete the sera of specific antibodies prior to exposure to the VLP attached to the plate. Depletion of immune sera with a polyomavirus-specific VLP permits determination of cross-reactivity of antibodies to different polyomaviruses. Using the VLP capture ELISA together with prior immunodepletion, evidence for infection with specific polyomaviruses can be obtained in a large collection of sera samples.

VLP-based assays indicate that infection with human polyomaviruses can occur in the first few years of life. Serologic surveys of populations for the detection of antibodies specific for JCPyV and BKPyV indicate that seroconversion takes place early in life.¹⁴⁶ Detection of maternal antibody in newborns diminishes within the first 3 months and is followed by evidence for newly acquired infection as early as the first year of life. Evidence for exposure continues to increase into adulthood, with titers corresponding to prior infection observed in approximately 50% to 80% of the sera tested.^{139,264,269} As evidenced by antibody titers, WUPyV and KIPyV infections can occur very early in life and then progressively become more common with age, with one report indicating 100% for KIPyV in healthy blood donors older than 50 years of age.^{193,195}

The VLP assay was initially used to detect evidence for prior infection with BKPyV and JCPyV in human sera and then expanded to search for evidence of prior infection with SV40. A high degree of cross-reactivity in human sera has been observed between VLPs from BKPyV and SV40 and to a smaller degree between JCPyV and SV40.^{34,139,273} Immune depletion of sera with BKPyV VLPs significantly reduces the titer of IgG-recognizing SV40 VLPs. Notably, reactivity of human sera against the African green monkey-derived lymphotropic polyomavirus (LPV) has been recognized for many years that was not appreciably depleted by preincubation with the VLP corresponding to SV40 or other known polyomaviruses. The discovery of human HPyV9, highly homologous to LPV, led to a direct comparison of sera reactivity for the

two corresponding VP1 proteins. Depletion with HPyV9 VLP removes most of the reactivity against monkey LPV.²⁶⁴

Antibodies to both BKPyV and JCPyV are quite prevalent in populated countries but less prevalent in remote populations. In a study analyzing sera from Amerindian tribes from remote regions of South America, a low percentage of samples were positive, demonstrating low titers compared to a collection of Japanese samples with the majority positive with high antibody titers, particularly to JCPyV.¹⁷⁴ It also seemed that introduction of the human polyomaviruses into the Amerindian population occurred at the time of human contact from other countries.

In general, detection of viral DNA by PCR is less sensitive than evidence for infection by serology-based testing. A direct comparison of evidence for infection using VLP assays, neutralization assays, and PCR-based detection of viral DNA isolated from the skin of more than 400 patients was performed. In this study, 65% had evidence for prior infection with MCPyV based on serology, but only 18% were positive by PCR amplification of DNA isolated from skin. This may be due to the inability of certain PCR primers to amplify all possible genomes of a given virus. Notably, nearly all patients with detectable amounts of MCPyV DNA on the skin had evidence for infection by serology against the virus.⁷⁷

Because excretion of the human polyomaviruses in the urine is relatively common, a number of studies have tested urine by PCR for the prevalence of BKPyV and JCPyV. Sequencing of the polyomaviruses has revealed variation in all regions of the viral genome, especially the NCCR and the sequences encoding the C-termini of large T antigen and VP1. Sequencing of BKPyV has identified four major subgroups with evidence for co-evolution with known migration patterns of human hosts.²⁷⁸

This approach demonstrated that excretion of the identical JCPyV virus occurred over 5 to 7 years in 19 different individuals and indicated persistent shedding rather than reinfection by different strains of JCPyV.^{136a} In addition, sequencing of JCPyV genomes revealed that the identical sequence was present in four of five families including parents and children, indicating that the virus spread horizontally within close quarters.²⁸³

Given that infection with JCPyV and BKPyV frequently occurs early in childhood among individuals living together, studies have been performed that reveal that polyomaviruses have co-evolved with humans.^{148,284} For example, a study collected urine samples from young and older individuals in Okinawa who had contact with American military and their families. The samples were analyzed using PCR to identify JCPyV DNA and nucleotide sequencing that could "type" variants of the DNA. One type was specific to Japan, while others were prominent in the United States. The results suggested that none of the JCPyV DNA types found commonly in the American population were present in any age group in Japan, suggesting that virus is not easily transmitted between populations.¹³⁶ Additionally, urine samples collected from second- and third-generation Japanese Americans living in Los Angeles revealed that strains of JCPyV more commonly detected in Japan were present in the second- and third-generation Japanese American families.²⁵⁵

Infection with MCPyV can also be traced back to childhood location by geographic areas based on sequences unique to specific polyomaviruses. Comparing the NCCR regions from different isolates revealed substitutions, small deletions, insertions, and duplications. Notably, strains detected in individuals from North

America or Europe could be distinguished from those from Asia, supporting co-evolution of viruses along with the host.²²⁶

CLINICAL FEATURES

Human diseases caused by polyomaviruses result from lytic infection of target cells including JCpV in the brain; BKpV in the kidney, bladder, and ureter; and TSPyV in the hair follicle. There is no evidence that the initial or primary infection by these polyomaviruses directly results in disease. Instead, it appears that the low levels of virus that are maintained by a healthy immune system can reach very high levels when an individual's immune system is affected by HIV-1/AIDS, organ transplantation, or immunosuppressive drugs. High levels of JCpV, BKpV, and TSPyV lead to destruction of infected tissues. Furthermore, high levels of MCPyV that can occur in immunocompromised patients may increase the chances for accidental integration of the viral genome into Merkel cells. The immunocompromised state of the patient may also disable mechanisms for effective clearance of the T antigen expressing Merkel cells, enabling it to advance to a cancer.

BKPyV-Associated Diseases

Reactivation of BKPyV infection is an important cause of illness in immunocompromised patients. BKPyV has been most consistently identified with kidney failure after renal allograft and hemorrhagic cystitis and ureteric stenosis in hematopoietic stem cell transplant (HSCT) recipients.^{5,6} BKPyV has also been implicated in ureteric stenosis and associated with kidney failure in HSCT patients.¹⁴³ In both patient groups, immunosuppressive drugs for graft protection allow reactivation of latent BKPyV in the urinary tract. BKPyV has also been associated with a limited number of cases of retinitis, nephritis, pneumonia, and encephalitis.

Approximately 40% of renal allograft recipients shed BKPyV in the urine either transiently or continually over weeks to months, with interstitial nephritis occurring in 10% of renal allograft recipients and graft loss caused by BKPyV infection in 1% to 2%. This syndrome is known as polyomavirus-associated nephropathy (PVAN) (Fig. 53.10). The definitive diagnosis of PVAN requires a kidney biopsy, although this test may lack sensitivity. Generally, viral cytopathic effects show nuclear inclusions in the tubular epithelial cells, with chromatin damage and enlarged nuclei indicating viral multiplication (Fig. 53.10). Such extensive virus growth causes damage and leakage to the tubules, which results in fluid in the interstitial spaces and gradually atrophy of the tubules and fibrosis.¹¹² PVAN is suggested by the presence of decoy cells, epithelial cells with viral inclusions, in the urine reflective of BKPyV replication and the presence of virus that can reach 10^7 virion particles per milliliter of urine. The presence of urine casts composed of polyomavirus aggregates or *Haufen* (German for “cluster” or “stack”) may also suggest the presence of productive BKPyV infection in the renal tubules.²⁴³

In the setting of failing kidney function, evidence for increasing levels of BKPyV in the blood and urine should prompt suspicion of PVAN. Quantitative PCR assays are used clinically to detect BKPyV viral load.¹³ The diagnosis of PVAN is suggested by BKPyV DNA in the blood (greater than 10,000 copies/mL) or VP1 mRNA (greater than 6.5×10^5 copies/ng total RNA) in the urine.¹¹³ In renal transplant patients, the incidence of BKPyV disease appears to correlate with high antibody titers in the donor. Evidence also suggests that there is greater vulnerability for graft loss if the recipient is seronegative for BKPyV and conversely that high levels of interferon- γ (IFN- γ)-secreting cells in the recipient are protective. It should be noted that both JCpV and MCPyV could be detected in the urine of patients with PVAN. However, it appears unlikely that JCpV and MCPyV are a significant cause of PVAN in the absence of BKPyV.^{120,170}

FIGURE 53.10. Polyomavirus-associated nephropathy. Photomicrographs illustrating BK polyomavirus (BKPyV) viral inclusions in the kidney of a transplant patient. **A:** Red arrows point to the intense inflammation associated with the viral infection that resembles acute cellular rejection with lymphocytes and eosinophils. The black arrows show the basophilic viral inclusions in the nuclei of tubular cells. **B:** Higher-power view of viral inclusions in the nuclei of tubular epithelial cells (arrows). (Courtesy of Kent Johnson, University of Michigan, Ann Arbor, MI.)

Active BKPyV infection in renal allograft patients at times mimics graft rejection, complicating the use of immune-suppressive drugs. Antirejection therapy can lead to graft loss due to an increase in viral multiplication.²¹³ Consequently, viral infection leading to interstitial nephritis and graft dysfunction may be sufficient reason to decrease immunosuppressive therapy and closely monitor acute rejection. A number of strategies for decreasing immunosuppressive drugs have been reported. A number of antiviral therapeutics have been tried without much success to reduce the severity of PVAN. There is a critical need for case-controlled studies.

HSCT patients undergo thorough immunosuppressive therapy before transplantation. The frequency of BKPyV disease is higher in adult allogeneic than autologous transplant patients. Both groups have BKPyV in their peripheral circulation.²⁶ In a comprehensive study of children between 7 and 17 years of age followed for nearly 1 year, all the BMT patients who developed hemorrhagic cystitis had antibodies to BKPyV prior to transplant, as did the marrow donors. However, there was a significant increase in IgM antibodies in cystitis patients compared with those with no signs of cystitis, indicating a new or reactivated infection. There was a correlation of the immune status to BKPyV of the donor and the risk of cystitis in the recipient. Donors of HSCT patients without occurrence of cystitis had higher antibody levels compared with donors of HSCT patients who did develop hemorrhagic cystitis.²⁶ However, as in the adult patients, there was not a direct correlation between BKPyV infection and hemorrhagic cystitis.

JCPyV and Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy (PML) is a demyelinating disease of immune-compromised individuals caused by a lytic infection of JCPyV in oligodendrocytes, the myelin-producing cells in the white matter of the human brain. Clinically, PML patients demonstrate a triad of neurologic

symptoms including muscle weakness and gait disturbance leading to hemiparesis, cognitive abnormalities consistent with a subcortical dementia, and sensory and visual deficits.⁷⁹ PML can occur at any time during life, even in childhood,¹⁹ although it usually is found in adults with severe immunodeficiencies. Life expectancy ranges from several months to 1 year, depending on the severity of the immunocompromised state and the viral burden in the brain.¹⁸ There is a strong correlation between longer-term survival defined as greater than 12 months and the levels of CD4/CD8 cells at the time of diagnosis.¹⁷ In patients with higher levels of CD4/CD8 cells, enhancement of lesions on gadolinium magnetic resonance imaging (MRI) scans may reflect inflammation in the brain due to immune cell recognition of viral antigens (Fig. 53.11). PML lesions are most frequently present in the cerebral hemispheres including the temporal, frontal, occipital, and parietal regions but also in the posterior fossa in the cerebellum and brainstem. PML lesions are typically located at the gray–white matter junction in areas of highest cerebral blood flow, implicating virus seeding by a hematogenous route. PML plaque lesions are asymmetrical, unlike the demyelinating lesions in multiple sclerosis (MS), due to gradual virus release from lytic infection that infects new oligodendrocytes by cell–cell contact.

The characteristic features of the histopathology of PML were first described in 1958.⁹ The demyelinated areas form multifocal plaque lesions that contain enlarged, hyperchromatic oligodendrocytes, macrophages, and bizarre astrocytes. Perivascular infiltrates, usually T lymphocytes, have also been described in some PML lesions. In heavily infiltrated regions, few infected oligodendrocytes can be detected. In these lesions, MHC class I has been identified on bizarre astrocytes while MHC class II has been found on macrophages, microglia, and endothelial cells.² Intrathecal antibody to JCPyV VP1 has been detected in the cerebrospinal fluid (CSF) of PML patients.²⁷⁶ These observations suggest immune clearance of infected cells with JCPyV antigen presentation in the infected brain.

FIGURE 53.11. Magnetic resonance imaging of progressive multifocal leukoencephalopathy (PML). **A, B:** T2-weighted images show a progressive increase in high-signal-intensity lesions over a period of 1 month in a patient with human immunodeficiency virus 1 (HIV-1) infection. Lesions are seen in the frontal lobe, the internal capsule, and the splenium of the corpus callosum with spread to the opposite hemisphere. **C:** Section from the frontal lobe of the same patient shows effacement of the cortical sulci and some midline shift suggestive of inflammation due to immune reconstitution inflammatory syndrome (IRIS).

Before the HIV-1/AIDS epidemic, PML was considered a rare disease in the United States with only several hundred cases reported. Up to the mid-1980s, the most common predisposing immune disorders in patients with PML were lymphoproliferative disorders, cancer, granulomatous and inflammatory diseases (e.g., sarcoidosis), and immune-suppressive drugs used in allograft recipients. With the advent of an increased population with severe immune deficiencies, particularly HIV-1/AIDS, the incidence of PML has risen dramatically, not only in the United States but also throughout the world. PML has been recognized in an increasing number of immunocompromised patients due to systemic lupus erythematosus, autoimmune vasculitis, non-Hodgkin Lymphoma, chronic lymphocytic leukemia, and bone marrow transplantation.^{3,137} More recently, PML has become a significant adverse event in autoimmune patients treated with immune-modulatory, biological therapies.^{79,173}

The highest number of cases of PML occur in patients infected with HIV-1, reaching as high as 5% of all AIDS cases and accounting for nearly 80% of all PML cases. PML has been the presenting AIDS-defining illness in 1% to 3% of HIV-1-infected individuals. Although the use of highly active or combined antiretroviral therapy (HAART or cART) has reduced the number of opportunistic infections, PML remains a substantial neurologic complication in HIV-1/AIDS patients. With the increased incidence of PML in AIDS patients, there has been the opportunity to evaluate the potential effect of HAART. Several studies have demonstrated that HAART can lead to improvement in clinical status, radiologic features, and a clearance of JCPyV DNA in the CSF. These observations suggest that eliminating HIV-1 burden may reduce the multiplication and spread of JCPyV into the brain either by direct viral interactions or an increase in immune reactivity to JCV.

There is a spectrum of JCPyV-induced brain diseases in HIV-1 patients treated with HAART, which include PML as well as a variety of focal lesions in the brain.³⁶ A surprising number of new PML cases have been reported within weeks to months after HAART was initiated, including some patients exhibiting immune reconstitution inflammatory syndrome (IRIS).²⁵⁷ The mechanism that underlies this observation is not known but may be associated with influx of latently infected immune cells into the brain upon immune reconstitution.²³⁹ It should be noted that BKPyV, WUPyV, and KIPyV have been detected in brain tissue of patients with HIV-1/AIDS, but it is unlikely that they contribute to the development of PML.¹²

Progression of neurologic symptoms including cognitive decline and motor dysfunctions with neuroradiologic evidence of white matter lesions is necessary but not sufficient to make a diagnosis of PML. Because white matter lesions identified in patients with AIDS are caused by HIV-1 and not by JCV-induced demyelination, evidence for JCPyV is critical. JCPyV viral DNA or protein must be demonstrated in the patient to make a definitive diagnosis. The mechanisms that account for the high incidence of PML in patients with HIV-1/AIDS are unknown. Whether a specific immune control of JCPyV latency that is deficient exists in patients with AIDS or a direct interaction occurs between the two viruses remains an open question.

Natalizumab, efalizumab, and rituximab are therapeutic monoclonal antibodies that can induce specific immune defects that can predispose the patient to PML.³³ Natalizumab is a humanized monoclonal antibody to the cellular adhesion α -4

(ITGA4, CD49D) integrin molecule. ITGA4 binds with β -1 (ITGB1, CD29) or β -7 (ITGB7) to form the very late antigen-4 (VLA-4) receptor. The antibody prevents T cells from binding to the VLA-4 receptors on endothelial cells and blocks extravasation into tissues such as the brain and colon. Natalizumab was approved by the U.S. Food and Drug Administration for relapsing, remitting multiple sclerosis and Crohn disease, an inflammatory bowel disorder; both are considered autoimmune-mediated diseases. During a phase III global trial, two patients with multiple sclerosis and one patient with Crohn disease developed PML.^{16,155} These patients had JCPyV detectable by PCR in the brain and peripheral blood. Prior use of immunosuppressive therapy with mitoxantrone, methotrexate, and azathioprine increases the risk of developing PML when treated with natalizumab.¹³⁴ Notably, prolonged treatment of multiple sclerosis with natalizumab can cause specific reactivation of JCPyV with increased frequency of detection in the urine.⁴²

While JCPyV isolated from kidney and urine contains the archetype NCCR without repeat elements, viruses obtained from PML brain tissue and blood from the same patient often contain direct tandem repeats. Interestingly, no two PML patients show identical nucleotide sequence arrangement, but each patient shows consistent nucleotide sequences.²¹⁴ There is also evidence for variations in the gene that codes for the VP1 capsid protein, with the suggestion that such alterations may lead to a more neurovirulent form of JCPyV.⁹⁷ In HIV-1/AIDS patients with PML, variations occur in the VP1 coding sequences but not the T antigen sequences that remain highly conserved.⁹⁴ Similar results were observed in natalizumab-treated patients.²¹⁴

Many laboratories and clinical centers have adopted PCR detection of JCPyV DNA in CSF samples in place of biopsy as the laboratory tool for confirmation of PML. Several recent studies have further shown that quantitative measurement of JCPyV DNA can also be used as a prognostic indicator of the progression of disease. Reduced viral genome copy number predicts long-term survival of PML patients. Viral DNA can be detected in longitudinal CSF samples months to even years after PML diagnosis, indicating that JCPyV can persist in the brain causing continued neurologic deficits regardless of immune responses.²¹⁸

There has been little progress in the treatment of JCPyV diseases. Antiviral treatment of PML patients has typically used nucleoside analogs in attempts to block JCPyV DNA replication. Cytarabine (cytosine arabinoside, ARA-C) has been used most frequently but without consistent results. Several reports had described remission of PML symptoms and brain lesions upon intrathecal administration of ARA-C. However, other patients treated with combined intravenous and intrathecal ARA-C did not show neurologic improvement, although in some cases there was a reduction of viral DNA in the CSF. Several other drugs have been used in patients with PML, including cidofovir. Recently, an esterified analog of cidofovir, 1-0-hexadecyloxypropyl (CMX001), has shown efficacy in reducing JCPyV replication in a human brain-derived cell line, SVG, and in primary human astrocytes at concentrations that were not toxic to the host cells.^{99,127} However, clinical use of CMX in PML patients has gut and hepatic toxicity, although it does reduce viral load in the CSF.

Reactivation of SV40 in monkeys with simian/human immunodeficiency virus (SHIV)-immunosuppressed rhesus monkeys can result in a PML-like disease. Monkeys that were

seropositive for SV40 prior to SHIV inoculation as well as a monkey that seroconverted for SV40 after inoculation with SHIV SV40 disease developed a PML-like disease.¹¹⁵ Infection with SV40 can also cause meningoencephalitis in SHIV rhesus monkeys.⁵⁵

Merkel Cell Polyomavirus and Merkel Cell Carcinoma

Merkel cell carcinoma (MCC) is a relatively rare skin cancer. Merkel cell carcinoma typically presents on sun-exposed areas of elderly patients. Intense and lifelong UV exposure from the sun seems to be a particular risk for Caucasian patients especially from Australia. Merkel cell carcinoma can occur in non-sun-exposed areas in young adults as well. Risk for developing Merkel cell carcinoma is increased in patients with severe immunocompromise including HIV-1/AIDS, solid organ transplantation, cancer, and chemotherapy. In particular, there is an increased risk for developing Merkel cell carcinoma in patients with chronic lymphocytic leukemia and vice versa.

The increased risk for developing MCC in HIV-1/AIDS patients prompted an intense search for a pathogen etiology. High-throughput sequencing of transcripts from four MCC specimens led to the identification of an open reading frame with weak homology to polyomavirus large T antigen. Complete sequencing of the viral genome revealed that it contained typical features of a polyomavirus with a large and small T antigen VP1, VP2, and VP3 and an NCCR containing the origin of replication.⁷⁸ In the original report, Southern blot detection of MCPyV DNA revealed random integration of viral DNA into the tumor host cellular DNA in 8 of 10 unique MCC tumor specimens. Significantly, a metastatic lesion had the same restriction fragment length pattern as the primary tumor, indicating

clonal integration of the polyomavirus DNA into the tumor cell DNA prior to metastasis. In addition, the integrated viral DNA incurred mutations in the large T antigen coding region that led to truncations of the large T antigen that retained the N-terminal J domain and LXCXE Rb-binding motif but eliminated the DNA-binding and helicase domains (Fig. 53.12A). The small T antigen sequence remained intact.

Since the original report, several labs have confirmed the presence of MCPyV in most if not all Merkel cell carcinomas studied.^{14,135,215a} Furthermore, expression of the truncated large T antigen and small T antigen is noted in a similar percentage of tumors.^{236,238} Frequently, the copy number of viral genomes can vary from as low as a single copy to several hundred copies or more when comparing one tumor to another. Furthermore, the expression levels of large T antigen vary from barely detectable to intense staining by immunohistochemistry (Fig. 53.12B). A few studies have reported that the presence of MCPyV in the Merkel cell carcinomas predicts a better prognosis. Of note, a recent expression profiling study noted that infiltration of the tumor with activated CD8 T lymphocytes predicted a better prognosis.²⁰⁴

A neutralization assay based on a pseudovirion generated by expression of the MCPyV VP1 and VP2 molecules that encapsulate a reporter plasmid capable of expressing luciferase²⁰² found that patients with Merkel cell carcinoma tended to have higher titers of serum antibodies against MCPyV than healthy adults. This suggests the possibility that Merkel cell carcinoma may have developed from a period of high MCPyV production. Serologies corresponding to prior exposure to MCPyV have been determined for healthy children and adults and for patients with Merkel cell carcinoma. Patients with Merkel cell carcinoma had the highest titers.²⁶³

FIGURE 53.12. Merkel cell carcinoma. **A:** The Merkel cell polyomavirus (MCPyV) viral DNA early region containing large and small T antigen is clonally integrated into the tumor cell DNA. Small T antigen remains intact while large T antigen undergoes mutations resulting in truncations that occur after the LXCXE RB1-binding motif. The alternative spliced form (57 kD) of large T antigen is shown. **B:** Merkel cell carcinoma with hematoxylin and eosin (H&E) (left panel) and immunohistochemistry stain (right) with a monoclonal antibody (Ab3) specific for MCPyV large T antigen showing expression in tumor cells. (Photomicrographs courtesy of Scott Rodig, Harvard Medical School, Boston, MA.)

Antibodies specific for MCPyV large and small T antigens were evaluated in patients with Merkel cell carcinoma and healthy controls. Antibodies specific for the T antigens were present in less than 1% of more than 500 control subjects, while 40% of 205 patients with Merkel cell carcinoma had antibodies specific for the shared residues in the N-terminus of large and small T antigen. Notably, antibody titers against the T antigens decreased in patients who remained disease free after treatment and rose in titers for patients with recurrent disease.²⁰³

Several Merkel cell carcinoma cell lines containing integrated copies of the MCPyV genome have been established. Expression of the small and large T antigen is required for the continued growth of these cell lines as RNAi depletion of either large or small T antigen caused growth arrest.^{116,238} Typical for all polyomaviruses, the MCPyV large T antigen contains an LXCXE Rb-binding motif that is required for binding to pRb. Expression of large T antigen mutant in the LXCXE motif disrupts binding to pRb and is no longer able to promote cell growth. As noted earlier, MCPyV small T antigen is capable of promoting phosphorylation of 4E-BP1 and increasing cap-dependent translation. This activity appears to be critical for MCC cell growth.

Treatment for localized Merkel cell carcinoma includes surgical excision and sentinel lymph node biopsy.¹⁶² Adjuvant radiation therapy may be used for larger lesions. Merkel cell carcinoma tends to be sensitive to radiation therapy and certain forms of chemotherapy including cisplatin and etoposide. However, after the initial responses to radiation or chemotherapy therapy, Merkel cell carcinoma tends to recur and become resistant to further treatment.

Trichodysplasia Spinulosa Polyomavirus Infections

Trichodysplasia spinulosa is an exceedingly rare skin disease observed in immunocompromised patients. The first case of trichodysplasia spinulosa was reported in 1999.¹¹⁰ Since then, less than 25 cases have been reported.¹⁷⁷ Trichodysplasia spinu-

losa occurs in adult and pediatric patients after solid organ transplantation on immunosuppressive treatment or with hematologic malignancy and chemotherapy.

The trichodysplasia spinulosa syndrome typically presents with alopecia especially of the eyebrows but can extend over the entire body. The hair follicles themselves can be inflamed. Instead of hair, fragile white spinous processes extend from the hair follicles (Fig. 53.13). Histology reveals changes within the hair follicle including plugging with keratotic debris and dystrophic inner root sheath cells that contain hyaline or glassy appearing granules. The hyaline material gives rise to the spinous processes.

The trichodysplasia spinulosa polyomavirus (TSPyV) was cloned by using rolling circle amplification of the spinous processes obtained from a newly described pediatric patient. TSPyV is a unique human polyomavirus most closely related to OraPyV1 and MCPyV.²⁶⁸ TSPyV DNA was detected by PCR from the skin of three kidney transplant patients. Importantly, the amount of TSPyV genomes detected was significantly higher in lesions (10^6 copies/cell) than in the occasionally positive samples from normal skin (less than 10^2 copies/cell).¹³⁸ Furthermore, detection of TSPyV VP1 protein was only observed in lesions. Electron micrograph imaging of hair follicles revealed small viral particles less than 45 nm suggestive of a polyomavirus rather than the larger papillomavirus particle size of 50 to 55 nm. The virus particles have been observed within the inner root sheath cells in the extracellular debris.¹⁷⁷

The frequency of TSPyV infection is probably similar to most other human polyomaviruses as determined by serology testing of more than 500 healthy subjects. The presence of IgG antibodies specific to TSPyV VP1 range from 10% in infants to 80% in adults,²⁶⁹ indicating the increasing incidence of a lifelong persistent infection. Notably, in 80 kidney transplant patients, 89% were serologically positive for TSPyV.

WUPyV and KIPyV and Respiratory Illness

WUPyV was originally discovered by high-throughput sequencing of respiratory secretions of patients with symptoms of acute

FIGURE 53.13. Trichodysplasia spinulosa. Affected nose with papules and spicules (**left panel**). Biopsy of a hyperkeratotic follicular papule from the forehead. The epidermis reveals enlarged, hyperplastic hair bulbs and hypercornification within a distended follicular infundibulum (hematoxylin and eosin [H&E] stain, 10×) (**right panel**). (Reproduced from van der Meijden E, Janssens RW, Lauber C, et al. Discovery of a new human polyomavirus associated with trichodysplasia spinulosa in an immunocompromised patient. *PLoS Pathog* 2010;6[7]:e1001024, under Creative Commons Attribution License.)

respiratory illness.⁹⁰ The initial survey found evidence for WUPyV DNA in 2% to 3% of more than 4,000 patients with acute respiratory tract infections.¹⁵⁶ However, these patients typically were infected with additional viruses including adenovirus and respiratory syncytial virus well known to cause respiratory illness.^{114,196} The detection of WUPyV and KIPyV in respiratory secretions from patients with respiratory illness was higher in patients immunocompromised by stem cell transplant.^{8,189} WUPyV and KIPyV were also more frequently detected in lymphoid tissue in autopsy specimens from patients with HIV-1/AIDS compared to controls without immunodeficiency.²³³ To date, it does not appear that infection with WUPyV or KIPyV leads to significant respiratory illness.

SV40 and Humans

From the mid-1950s to 1963, the simian polyomavirus SV40 was unknowingly introduced into 100 million people that had received contaminated poliovirus vaccines.²³⁰ Because SV40 is tumorigenic in rodents and can transform human cells in culture, there has been concern about whether SV40 can contribute to cancer development in humans vaccinated with the contaminated polio vaccine. There has also been controversy regarding whether SV40 can replicate and establish a productive infection in humans.

Follow-up studies from the initial polio vaccination efforts have concluded that there has not been an increase in neoplasias over three decades in the population that was directly exposed to SV40 compared with matched age, gender, and geographical control populations not exposed to SV40.²³¹ A retrospective cohort study of data collected by programs designed to track tumor incidence in specific populations did not find any association between SV40 exposure and increased risk.²⁵⁰ The FDA Office of Vaccine Research and Review convened a meeting of international authorities to discuss the topic of SV40 in the human population and the technical approaches needed to evaluate its presence as an infectious agent and role, if any, in human tumors.²⁴¹ The Institute of Medicine also published a study that concluded that the epidemiologic evidence regarding SV40 infections in humans is inconclusive and recommended additional research.²⁴⁹ There have been sporadic reports that SV40 DNA and large T antigen protein can be identified in human tumors such as ependymomas, osteosarcomas, mesotheliomas, and choroid plexus papillomas.^{20,32,58,158} However, unlike the frequent presence of integrated MCPyV viral genome in Merkel cell carcinoma, there have been no reports of integrated SV40 viral genomes in human tumors.

It is not certain if SV40 can establish a persistent infection in humans. While SV40 can replicate at very low levels in human fibroblasts and mesothelial cells in culture, it does not appear to be capable of replicating in lymphocytes.^{22,232} Notably, while BKPyV and JCPyV are frequently detected in human sewage, the presence of SV40 has not been reported.²⁴ In addition, while some human sera are reactive against SV40 VP1, suggesting a sustained infection, most of this activity can be depleted by preincubation with BKPyV or JCPyV VP1.^{139,216}

Association of BKPyV and JCPyV with Human Tumors

Reports have identified BKPyV DNA in primary brain tumors, osteogenic sarcomas, colorectal carcinomas, urinary tract neoplasms, and meningiomas. However, BKPyV DNA has also

been described in normal brain, bone, peripheral blood, and gastrointestinal and urinary tracts, so it is difficult to draw conclusions on the importance of its presence in tumor tissues. BKPyV has also been detected in preneoplastic prostatic tissues.⁵⁷ It is not clear if BKPyV contributes to development of the preneoplastic state or whether these cells represent an idealized host cell that supports BKPyV replication.

Because experimental infection with JCPyV induces glial tumors in nonhuman primates, the major focus of interest in the oncogenic potential for JCPyV in humans has been the brain. There have been several reports of PML patients with multiple astrocytomas or oligodendroglioma, along with evidence of anaplastic astrocytes.⁸⁵ However, this occurrence is not common in PML, nor has there been evidence of JCPyV in these tumors or in bizarre or anaplastic astrocytes. A study examined 225 human brain tumors, predominantly gliomas, for nucleotide sequences for JCPyV, BKPyV, and SV40. All specimens were evaluated in a blinded manner by two independent laboratories. Although one lab detected polyomavirus in nine tumors, the other lab could not confirm these results. No tumor had polyomavirus DNA identified by both laboratories.²¹⁷

In addition to brain tumors, the presence of JCPyV DNA was found in high copy number in colorectal tumor tissue compared with normal, noninvolved colon tissue from the same patient.¹⁵² Similar to the presence of BKPyV in preneoplastic prostate lesions, the presence of JCPyV in colon carcinoma cells may represent a passenger and not a driver during oncogenesis.

Avian Polyomavirus and Disease

Hemorrhagic nephritis and enteritis of geese develops rapidly after infection with GHPyV. Typical symptoms of infected birds include generalized edema, gout, hemorrhagic enteritis, interstitial nephritis of the kidney tubular epithelium, and disruption of lung, feather follicle, and endothelial cells. Lymphoid tissues can also be affected with depletion of most lymphocytes. These features have been observed in naturally and experimentally infected birds.^{151,201} In addition to GHPyV, infection with APyV, FPyV, and CPyV are associated with fatal disease often including hepatitis, ascites, enteritis, and nephritis.¹³¹

PERSPECTIVE

Since Ludwig Gross first described the parotid agent or MPyV in 1953, the polyomaviruses have proven to be a rich model system for understanding fundamental biological processes in eukaryotic cells. In addition to the insights that have contributed to our understanding of transcription factors and enhancers, RNA splicing and polyadenylation, and DNA replication, the study of polyomaviruses has enriched our understanding of tumor suppressors, oncogenes, tyrosine kinase signaling, immunity, and tumorigenesis. The intensive study of polyomavirus cell receptors, entry, and trafficking through the cell has brought remarkable insights that have challenged previously held models. Importantly, the information gained by study of polyomaviruses has provided critical insights of human disease. As the population of immunosuppressed individuals increases due to HIV-1/AIDS and developments in transplant medicine, the incidence of clinical polyomavirus disease continues to climb. A clear example of this has been the occurrence of

JCPyV-induced PML in patients with multiple sclerosis or Crohn disease who were treated with an antibody that blocked T lymphocytes from binding the VLA4 receptor through the $\alpha 4$ integrin molecule.

Continued investigation into the interaction between polyomaviruses and their hosts will be crucial in framing our ability to intervene with patients in the future. Given new technology and model systems, it should be possible to develop high-throughput screens to identify more effective compounds that inhibit the viral life cycle. It is imperative that evidence-based clinical studies, guided by impeccable cellular- and molecular-based studies, are implemented to benefit immunocompromised patients suffering with polyomavirus-related diseases.

The contribution of MCPyV to Merkel cell carcinoma deserves special mention. To date, all studies indicate that expression of the MCPyV small T antigen and a truncated form of large T antigen is present in at least 80% of all Merkel cell carcinomas. Consistent with the large body of literature on polyomavirus-mediated transformation, MCPyV is clonally integrated into the Merkel cell carcinoma cells in a manner that enables persistent expression of the T antigens. There are many questions that remain unanswered regarding the role of MCPyV T antigens in Merkel cell carcinoma. In addition, it is not understood what the contributions of age, UV exposure, and immunosuppression are to the risk for developing this cancer. Furthermore, it is not known what is the normal host cell or tissue type for MCPyV and what is the special relationship with Merkel cells. Also, the factors in the host and virus that sustain lifelong infection but permit reactivation of polyomavirus infection remain to be defined not only for MCPyV but also for all polyomaviruses.

The recent discoveries of new polyomaviruses in humans, primates, marsupials, and birds have brought renewed vigor to the field. It is likely that more polyomaviruses will be discovered. More importantly, it can be expected that investigation of the new and previously discovered polyomaviruses will continue to bring important new and fundamental insights into biology and disease. It can certainly be concluded that the polyomaviruses have paid huge dividends in the amount of knowledge they have yielded. Consequently, the future seems to hold great promise that study of polyomaviruses will continue to help us demystify fundamental cellular processes and give direct benefits to patients whose active infection becomes life threatening.

Prophylactic Vaccination

The papillomaviruses (PVs) comprise a group of nonenveloped epitheliotropic DNA viruses that induce benign lesions of the skin (warts) and mucous membranes (condylomas). Some PVs have also been implicated in the development of epithelial malignancies, especially cancer of the uterine cervix, other tumors of the urogenital tract, and upper airway cancers. The recognition that PVs are an important cause of human cancer has led to the development of a preventive virus-like particle (VLP)-based vaccine targeted to the human papillomavirus (HPV) types most often found in the cancers. This chapter focuses primarily on the HPVs.

HISTORY

Warts were known to the ancient Greeks and Romans. Their infectious nature was recognized, but until the nineteenth century, genital warts were usually considered to be a form of syphilis or gonorrhea. The viral nature of human warts was demonstrated in the early 1900s when cell-free filtrates from lesions were shown to transmit the disease.¹¹⁰ PVs were subsequently identified in a variety of vertebrate species in addition to humans.^{346,592} Because PVs are species-specific in their host range, it has not been possible to study the biology of HPVs in animals.

The first animal PV was identified in the 1930s by Richard Shope, who characterized the transmissible nature of cutaneous papillomas arising in wild cottontail rabbits.⁵⁵³ The Shope papillomavirus, now designated the cottontail rabbit papillomavirus (CRPV), was the first DNA tumor virus identified. Shope's research also showed that although systemic injection with papilloma suspensions did not produce detectable infection, it could induce serum neutralizing antibodies and protect rabbits against high-dose cutaneous viral challenge.⁵⁵² These findings laid the groundwork for believing that a preventive vaccine against a PV could be based on the induction of humoral immunity. In addition to causing benign papillomas, some warts induced by CRPV were observed to undergo malignant progression,^{513,599} and for the next two decades, CRPV was an important model for the fundamental study of viral tumorigenesis.^{328,598} However, its use as a model tumor virus was largely supplanted by the discovery in the late 1950s of the polyomaviruses, which could replicate in cultured cells and induce morphologic transformation *in vitro*, in contrast to CRPV, and were tumorigenic for experimental animals.⁴¹⁷

In addition to CRPV, the rabbit oral papillomavirus (ROPV) was also identified in the 1930s as a distinct virus of domestic rabbits.⁴⁵⁹ ROPV infected the oral mucosa of rabbits but not their skin, whereas CRPV had the opposite host range, and neither virus was infectious for heterologous hosts.

Furthermore, ROPV was not oncogenic, in contrast to CRPV, and neutralizing antibodies against one virus were shown not to be neutralizing for the other. The research on CRPV and ROPV thus established the multiplicity of PVs, the narrow host range of PVs to sites with stratified squamous epithelia that were cornified (skin) or noncornified (mucosa), and the notion that protection against one PV may not confer protection against another PV.

Although the PVs were studied less intensively in the 1950s and 1960s, that period was associated with some important advances, including the physicochemical analysis of PV virions and the demonstration that PV replication was associated with the differentiation process of the infected epithelium.^{379,515} However, it was the advent of molecular cloning in the 1970s that initiated more extensive studies of PVs. This technical advance enabled investigators to partially circumvent the inability to culture PVs, as the cloning of PV genomes greatly enhanced the ability to study their biologic and biochemical properties. The sequencing of the cloned PV genomes led to the identification of open reading frames (ORFs) as putative viral genes and permitted investigators to determine the function of viral genes by reverse genetics, resulting in a much wider interest in PV research.^{97,125,126} The bovine papillomavirus type 1 (BPV1) represented the standard PV for initiating these studies because the virus induced focal transformation of established rodent cell lines.^{45,163} The molecular cloning of the HPV genomes also led to the recognition that there were multiple HPV genotypes, and that a subset of these types was closely associated with human cancers, including cervical cancer.^{56,162,446} The appreciation of their medical importance, combined with improved tools for analyzing PVs, further enhanced the utility of PVs as a model of viral tumorigenesis. Although the study of animal PVs continues to bring new information to the field, the medical importance of HPVs has shifted emphasis toward the analysis of HPV, especially when it was established that the biochemical properties of some nonstructural viral proteins differed from those of their BPV-1 counterparts.^{165,525}

CLASSIFICATION

Historically, the PVs were classified together with the polyomaviruses as a single family, the *Papovaviridae*. This grouping arose because although PV genomes and virions are larger than those of polyomaviruses, the viruses share many features, including a double-stranded circular DNA genome, an icosahedral capsid composed of 72 pentamers, a nonenveloped virion, and the nucleus as the site of viral replication and virion assembly. However, sequencing of PV genomes indicated that although PVs share a common genetic organization, they differ from that of polyomaviruses and have no major sequence homology to polyomaviruses, and PV transcription is unidirectional, in contrast to the bidirectional transcription of polyomaviruses. Recognition of these differences, and others, have led to PVs being designated as a distinct family, the *Papillomaviridae*, by the International Committee on the Taxonomy of Viruses (ICTV) in 2000.⁶²⁸

PVs have been isolated from many mammalian host species, birds, and reptiles, but thus far have not been identified in nonvertebrates. There are hundreds of PV types (as defined in

the next paragraph). PVs are species-specific and many different PV types can infect a given host species. HPVs have been analyzed most intensively; by 2010, 120 different HPV types had been identified, and there are likely to be more.³⁹

PVs are classified primarily according to the host species they infect and have been traditionally referred to as types based on their DNA sequence. A distinct type is one whose L1 DNA sequence is at least 10% different from that of other HPV types. The PV genomes have been organized phylogenetically based on their DNA sequence (Fig. 54.1; 44), according to the comparative homology of the L1 ORF. Similar phylogenetic relationships are also seen when homologies between other regions of the genome are compared, as PVs appear to have arisen primarily via point mutations scattered throughout the genome, rather than via recombination between PVs.⁹¹ These similarities are consistent with the conclusion that PVs have accompanied their host species during evolution and have evolved with them.⁴⁰ Although all PVs share a similar genetic organization, the L1 DNA sequence identity is just over 40% between the most divergent genomes. On the other hand, two very closely related isolates may differ by only a single nucleotide. The current classification attempts to provide logical designations to cover this wide range of homology: genus, species, type, subtype, and variant. The broadest category is a *genus*. PVs are divided into 29 genera, each of which is designated by a letter of the Greek alphabet (Fig. 54.1). Within a given genus, the L1 DNAs of all members share more than 60% identity; conversely, they have less than 60% identity with members of other genera. A *species* is designated for those PVs within a given genus that share 60% to 70% identity. A viral *type* within a species has 71% to 89% identity with other types within the species. Within a type, there can be *subtypes*, which share 90% to 98% identity, and *variants*, which have more than 98% identity. Although there are relatively few subtypes,⁴⁰ many variants have been identified for HPV-16, the type that has been examined in greatest detail because of its medical importance.¹⁰⁰

Using this classification, HPVs are clustered among 5 of the genera: alpha, beta, gamma, mu, and nu, with the other 24 genera being occupied exclusively by animal PVs.³⁹ The host species associated with each PV genus tend to be closely related evolutionarily. Therefore, PVs that infect nonhuman primates are found within the genera that include HPVs, and some HPVs are more closely related to nonhuman primate viruses than to some of the other HPVs in the genus. The HPVs of greatest medical importance, that is, those that are associated with genital and mucosal cancers, are members of the alpha genus. Most alpha PVs primarily infect genital and nongenital mucosal surfaces and the external genitalia. This group of PVs is often referred to collectively as the “genital-mucosal” types. The types that are associated with cervical cancer, often designated as “high-risk” types, are found in species 5, 6, 7, 9, and 11.^{423,529} HPV16, the type found most frequently in cervical cancer, is a member of species 9, whereas the next most common cancer-associated type, HPV18, is a member of species 7. HPV-6, which causes most cutaneous genital warts, is a species 10 member.

In contrast to most species of the alpha genus, members of alpha species 4 (HPV2, -HPV27, and HPV57) are primarily infectious for nongenital skin. The beta, gamma, mu, and nu viruses also infect nongenital skin. The beta HPVs

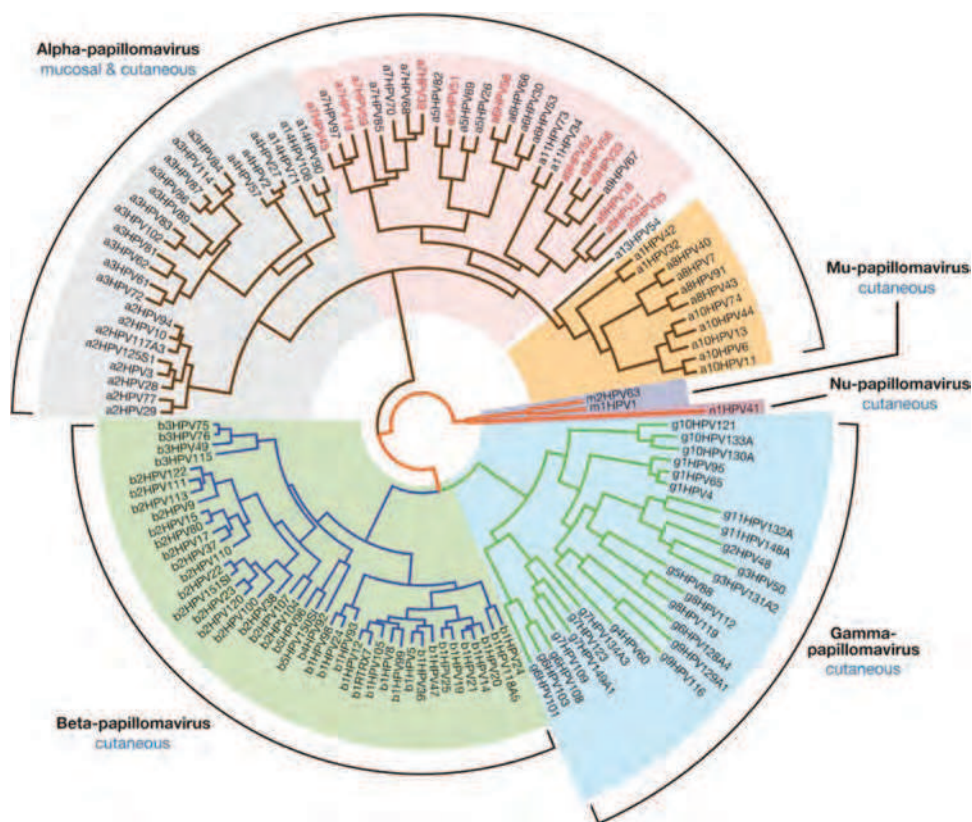

FIGURE 54.1. Phylogenetic tree demonstrating the evolutionary relationship among human papillomaviruses (HPVs). HPVs comprise five groups with different epithelial tropisms and disease associations. The alpha papillomaviruses include the low-risk mucosal types (many of which are within the orange-shaded branch) that cause genital warts, and the high-risk mucosal types (contained within the branch highlighted with pink shading) associated with anogenital preneoplasias and cancers. Although the cutaneous HPV types—most of which are contained within the gray (alpha), green (beta), and blue (gamma) shaded branches—are not generally associated with cancers, certain beta types have been implicated in the development of nonmelanoma skin cancers (NMSC) in immunosuppressed individuals and in epidermodysplasia verruciformis (EV) patients. The lower case letter and number preceding the HPV type refer to its genus and species. (Generated by John Doorbar; reprinted from Doorbar J, Quint W, Banks L, et al. The biology and life-cycle of human papillomaviruses. *Vaccine* 2012;30(Suppl 5):F55–F70, with permission.)

include those that are often designated epidermodysplasia verruciformis (EV) specific, because they cause lesions mainly in patients with EV, a genetic susceptibility to widespread non-genital HPV lesions. Some PVs, including many members of the beta and gamma species, may behave as commensal agents, as they are frequently isolated from normal skin or plucked hair from humans and animals.^{12,59}

The PVs in the delta genus, which include BPV1 and some other PVs of ungulates, cause fibropapillomas, rather than papillomas. This distinct pathology results from a proliferative dermal fibroblastic component under the epithelial portion of the lesion, because members of this genus induce nonproductive transformation of the fibroblasts, in addition to the productive infection of the overlying epithelium. The ability to transform nonepithelial cells is not species-specific. It can lead to the induction of nonproductive fibroblastic tumors in heterologous hosts under natural conditions, as in equine sarcoid of horses (from BPV1 or BPV2), or experimental hosts, such as hamsters. It also endows viruses such as BPV1 and BPV2 with the ability to induce focal transformation of cultured rodent cells.

VIRION STRUCTURE

Papillomaviruses are small, nonenveloped, icosahedral DNA viruses that replicate in the nucleus of squamous epithelial cells. The PV particles are approximately 60 nm in diameter (Fig. 54.2). The virion particles consist of a single molecule of double-stranded circular DNA about 8,000 base pairs (bp) in size, contained within a spherical protein coat, or capsid, and composed two viral proteins L1 and L2. The DNA constitutes approximately 12% of the virion by weight, accounting for their density in cesium chloride of 1.34 g/mL.¹¹⁶

Fine structural analysis by cryoelectron microscopy (cryo-EM) and three-dimensional image reconstruction techniques has revealed that the viruses consist of 72 pentameric capsomers arranged on a $T = 7$ surface lattice.^{22,621} The capsomers comprise five L1 molecules with an L2 molecule occupying the axial lumen.⁷³ As with the polyomavirus capsids, the capsomers exist in two environments, one capable of making contact with six neighbors as observed in the 60 hexavalent capsomers and the other with five neighbors in the 12 pentavalent vertex capsomers (Fig. 54.3). Analysis of proteins in the virus particle

FIGURE 54.2. Electron micrograph of bovine papillomavirus 1 (BPV1) virion particles (55 nm in diameter). (Reprinted from Baker TS, Newcomb WW, Olson NH, et al. Structures of bovine and human papillomaviruses—analysis by cryoelectron microscopy and three-dimensional image reconstruction. *Biophys J* 1991;60:1445–1456, with permission.)

showed that the viral DNA is associated with cellular histones to form a chromatin-like complex.^{172,469}

VLPs can be produced from different PVs by expressing L1 alone using mammalian or nonmammalian expression systems.^{234,311,511} The morphology of VLPs containing only L1 appears identical to intact virus particles in low-resolution cryo-EM reconstructions.²³³ The structure of a truncated T = 1 HPV16 L1 VLP containing 12 pentamers has been solved by x-ray crystallography to 3.5 Å resolution.⁹⁹ The structure of

full-size BPV1 virions was recently solved to 3.6 Å resolution using cryo-EM.⁶⁶⁸

GENOME STRUCTURE AND ORGANIZATION

The genomes of many of the human and animal papillomaviruses have been sequenced in their entirety, and the genomic organization of each of the papillomaviruses is similar. One characteristic of the genomic organization of all papillomaviruses is that all of the ORFs are located on one strand of the viral DNA, thus indicating that all of the viral genes are located on one strand. Transcriptional studies indicate that only one strand serves as a template for transcription.

The coding strand contains approximately 10 designated translational ORFs that are classified as either early (E) or late (L) ORFs, based on their location in the genome. The early region of the papillomavirus genomes encodes viral regulatory proteins including those viral proteins that are necessary for initiating viral DNA replication. The L1 and L2 ORFs encode the viral capsid proteins and are expressed only in productively infected cells.²¹ The position, size, and function of many of the ORFs are well conserved among the various PVs that have been sequenced and studied in detail thus far. The functions of the individual ORFs, the functions of which have been well characterized, are described in more detail in the appropriate sections of this chapter.

There is a region, of approximately one kilobase, in each of the papillomavirus genomes that contains no ORFs. This region has been referred to by several terms including the long control region (LCR), the upstream regulatory region (the URR), and the noncoding region. This region contains the origin of DNA replication as well as important transcription control elements. The genomic organization of HPV16 is shown in Figure 54.4.

VIRUS REPLICATION

The PVs are highly species-specific and have a specific tropism for squamous epithelial cells. The productive infection of cells

FIGURE 54.4. HPV16 genomic map. The numbers inside the circle indicate the nucleotide positions. The individual open-reading frames (ORFs) of the early (E) and late (L) regions are depicted as areas outside the double-stranded circular genome. Only one strand is transcribed, and transcription occurs in the clockwise direction. The early promoter (P_{97}) is indicated by an arrow at the approximate nucleotide position of the RNA initiation site. P_{670} is the late promoter whose initiation sites map within the E7 ORF. The long control region (LCR) designates the long control region that contains the origin of DNA replication. The hatch marks indicate the four E2 binding sites within the LCR.

by the PVs can be divided into early and late stages. These stages are linked to the differentiation state of the epithelial cell. The specific tropism of the PVs for squamous epithelial cells is evidenced by the restriction of the viral replication functions, such as vegetative viral DNA synthesis, the production of viral capsid proteins, and the assembly of virions to differentiated epithelial cells. The close link of the papillomavirus life cycle with the differentiation program of the squamous epithelium is depicted in Figure 54.5.

The basal cell is the only cell in the squamous epithelium capable of undergoing cell division. Therefore, the virus must infect the basal cell in order to establish a persistent lesion. By *in situ* hybridization, it has been demonstrated that the viral DNA is indeed present within the basal cells and the parabasal cells of a papilloma.⁵³⁶ Furthermore, using probes to the early gene regions of the PVs, viral transcripts have been detected in the basal cells of the epidermis,⁵⁸⁴ and at least some early viral protein is found in basal cells.⁷⁹ Late gene expression, synthesis of capsid proteins, vegetative viral DNA synthesis, and assembly of virions occur only in terminally differentiating squamous epithelial cells.

Virion Attachment, Entry, and Trafficking

Papillomaviruses have a unique infectious process that is intimately linked with their life cycle in stratified squamous epithelia. As noted above, productive papillomavirus infection

is thought to require infection of the basal layer cells of the epithelium.¹⁵² To achieve selective infection of basal keratinocytes, the virions have evolved to preferentially bind initially to heparan sulfate proteoglycans (HSPGs) on the basement membrane exposed at sites of epithelial trauma or permeabilization, rather than to cells (Fig. 54.6).^{285,500} *In vitro*, the capsids bind directly to most epithelial cell lines in an HSPG-dependent manner.²¹² This difference probably reflects the adaption of *in vitro* propagated epithelial cells to the expression of HSPGs with modifications that resemble those that are normally found only on basement membrane *in vivo*.¹³⁰ Basement membrane binding induces a conformational change in the capsid that exposes a highly conserved N-terminal L2 peptide motif to cleavage by furin or the closely related proprotein convertase 5/6.³¹⁰ According to one model, cleavage induces a conformational change that exposes a capsid-binding site (probably on an L1 surface) for an as yet unidentified cell-surface receptor on keratinocytes and other cell types.³¹⁰ Alternatively, a recently proposed model suggests that the virions may interact with cell surfaces as high molecular weight complexes also containing cleaved HSPGs and bound growth factors through an interaction with a variety of growth factor receptors.⁵⁹⁴ There is a remarkably long delay between cell surface binding and viral genome transcription of 1 to 3 days, both *in vivo* and *in vitro*.^{129,500} Internalization of the capsids from the cell surface takes at least 2 to 4 hours, and is very asynchronous, with some capsids remaining on the surface for a much longer time.¹²³ *In vitro* studies indicate that the capsids are transported on the cell surface from filopodia at the leading edge of migrating cells to the central cell body via linkage to actin retrograde flow.⁵²⁶

The endocytic pathway involved in internalization and intracellular trafficking by PV capsids is controversial. Most studies have observed trafficking to acidified late endosomes either via clathrin-dependent or clathrin-independent uptake (Fig. 54.7).^{57,129,561} However, one study has implicated caveolin-dependent uptake with eventual trafficking to the endoplasmic reticulum,³⁴⁷ whereas another has suggested that tetraspanin-enriched microdomains may be involved in endocytosis.⁵⁷⁵ Several cell factors have been implicated in internalization and trafficking. These include cyclophilin B, a peptidyl-prolyl *cis/trans* isomerase, being required for exposure of the furin cleavage site in L2⁴²; sorting nexin 17, an adaptor protein involved in endosome cycling that inhibits routing of the capsids to lysosomes³⁵; and FAK, a focal adhesion kinase.¹ At least partial uncoating occurs in Lamp-2–positive late endosomes, but not until at least 8 to 12 hours after cell surface binding.¹²⁷ L2–genome complexes escape the late endosomes, whereas the genomes packaged in L1-only capsids do not.²⁹³ A conserved C-terminal L2 peptide with strong membrane penetrating and disrupting activity *in vitro* may be directly involved in endosomolysis. In addition, the activity of the transmembrane protease γ -secretase is required for infection, perhaps functioning in endosome escape.²⁹⁶ Movement through the cytoplasm to the nucleus likely occurs along microtubules in association with the motor protein dynein.¹⁸³ The fact that infection, at least *in vitro*, requires cell division has led to the conjecture that entry of the L2–genome complex into the nucleus may require nuclear envelope breakdown during mitosis, rather than active transport through nuclear pores.⁴⁸⁵ After cell division, the L2–genome complexes predominantly localize to specific nuclear structures, N10 bodies (also designated promyelocytic leukemia protein (PML) oncogenic domains, or

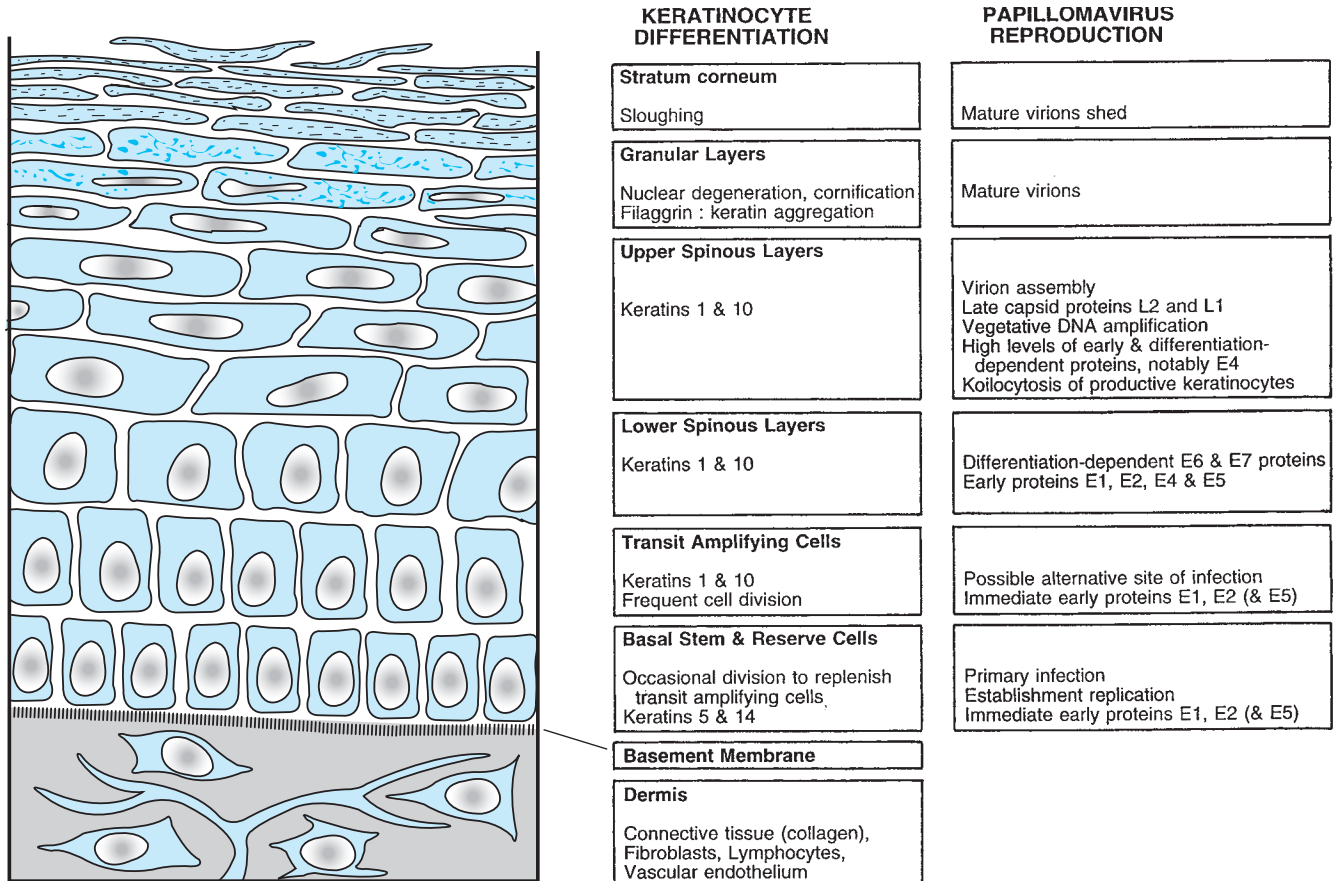

FIGURE 54.5. Differentiation of normal cutaneous squamous epithelium and papillomaviral activities in productively infected benign lesions. The various epithelial strata and the host differentiation, stage-specific, gene-expression profile are indicated in the left and center panels. In nonkeratinized squamous epithelia, such as cervical or laryngeal, keratins 4 and 13 are expressed in the place of keratins 1 and 10 in the differentiated cells. Although profilaggrin is expressed, there is no granular layer or stratum corneum in nonkeratinized squamous epithelia. The viral activities in the corresponding strata during productive infection shown on the right have been determined or inferred from *in situ* hybridization studies. FIGURE 54.6. Model of in vivo papillomavirus infection. The virion first binds to heparan sulphate proteoglycans (HSPGs) on the basement membrane exposed after disruption. This induces a conformational change exposing a site on L2 (depicted in yellow) susceptible to proprotein convertase (furin or PC5/6) cleavage. After L2 cleavage, an L2 neutralizing epitope is exposed and a previously unexposed region of L1 binds to an unidentified secondary receptor on the invading edge of the epithelial cells.

FIGURE 54.7. Infectious process after cell binding. After binding to a cell surface receptor (a), the virus enters the cell via an endocytic pathway (b) and within 4 hours localizes in the early endosome (c). By 12 hours the virus uncoats within the late endosome and the viral genome complexed with L2 is released (d). The L2–genome complex traffics through the cytoplasm, perhaps via microtubules, and enters the nucleus by 24 hours (e). After nuclear entry, the complex co-localizes with ND10 and viral genome transcription begins (f).

PODs).¹²⁷ This localization promotes transcription of the viral genome. Potentiation of PV infection by association with ND10 bodies contrasts with the inhibitory activity of these structures in infections by herpes viruses, which target PMLs for degradation early in infection.¹⁷¹

Viral Transcription

The replicative phase of the papillomavirus life cycle is tightly linked to the differentiation program of the squamous epithelium. Historically, BPV1 served as the prototype for analyzing the papillomavirus transcription program. The studies have been carried out in a variety of systems, including viral RNAs from rodent cells transformed by BPV1 as well as those from infected wart tissues. More recently viral transcription studies have been extended to some of the HPVs associated with genital tract lesions—such as HPV11, HPV16, HPV18, and HPV31—by using HPV-positive clinical lesions, xenograft tissue in nude mice, cervical carcinoma cell lines, as well as organotypic culture systems. This portion of the chapter on transcription focuses largely on HPV16 and HPV31, both of which have been extensively analyzed by *in vitro* culture techniques.⁴¹¹

Viral RNAs and Promoters

Papillomavirus transcription is complex due to the presence of multiple promoters, to alternate and multiple splice patterns, and to the differential production of messenger RNA (mRNA) species in different cells.

A transcription map of HPV31 is shown in Figure 54.8. As with BPV1, multiple promoters are involved in generating the various mRNA species for the genital tract HPVs. For HPV31, P₉₇ is the major promoter active in nonterminally differentiated cells. This promoter, which directs the expression of E6 and E7 as well as several other early gene products, is analogous to P₉₇ of

HPV16 and P₁₀₅ of HPV18. Upon differentiation of immortalized keratinocytes harboring episomal HPV-31 DNA, there is activation of the differentiation-dependent, late promoters, P₆₇₀ for HPV16 and P₇₄₂ for HPV31, that direct the expression of the late gene products, including E4, L1, and L2, as well as an increase in the level of the E1 mRNA.^{321,517}

An important difference in the structures of the E6 and E7 mRNAs and in the manner by which they are expressed distinguishes the “high risk” and “low risk” HPV types. For the “high risk” HPVs such as HPV16 and HPV18, a single promoter (P₉₇ for HPV16 and HPV31, or P₁₀₅ for HPV18) directs the synthesis of mRNAs with E6 and E7 intact or with splices in the E6 gene (Fig. 54.8). The species with E6 intact could be translated into E6 but not E7 since there is insufficient spacing for translation reinitiation. The mRNAs with the spliced E6 splice the 5′ end of the E6 ORF (referred to as E6*) to a translation frame with stop codons that provide sufficient spacing for translation reinitiation of the E7 ORF and are therefore likely to represent the E7 mRNAs. In contrast, the E6 and E7 genes of the “low risk” HPVs such as HPV6 and HPV11 are expressed from two independent promoters.¹⁰⁵

Regulation of Transcription (Cis Elements)

Papillomavirus transcription is tightly regulated by the differentiation state of the infected squamous epithelial cell. This is evident from the analysis of the differential expression of viral RNAs in cells from the different levels of the epithelium in warts.¹⁰⁷ It is also evident from studies of infected keratinocytes using organotypic and suspension tissue culture systems that permit epithelial cell differentiation.^{149,321,410} Proper transcription of the viral genome is dependent upon the differentiation state of the epithelial cells and on cellular transcription, splicing, and other RNA processing factors.³⁷³

FIGURE 54.8. Transcription map of HPV31.^{266,267,321,448} A linearized version of the genomic map is shown at the top. Transcripts initiated at the early viral promoter, designated P₉₇, are expressed in the nonterminally differentiated cells in the lower portion of the epithelium, whereas those initiating from the late promoter (P₇₄₂) are expressed upon differentiation in the cells committed to the replication of the progeny virions. (Reproduced from the PAVE transcription maps, <http://pave.niaid.nih.gov>.)

The LCR (also referred to as the URR) region of papillomavirus contains enhancer elements that are responsive to cellular factors as well as to virally encoded transcriptional regulatory factors. Each of the viral LCRs that have been studied in detail have been found to contain constitutive enhancer elements that have some tissue or cell-type specificity. These constitutive enhancer elements play an important role for the initial expression of the viral genes after virus infection and may also be important in the maintenance of viral latency. A number of transcription factor binding sites have been identified in the LCRs of the various papillomaviruses that have been carefully studied. Included among them are sites that bind AP1, SP1, Oct-1, and YY1, among others.^{38,373} The HPV16 LCR has also been shown to contain nuclear matrix attachment sites that may be important for controlling viral gene expression.⁶⁰⁴ In addition to the binding sites for cellular transcription factors, the LCR contains binding sites for the virally encoded E2 regulatory proteins and the origin of DNA replication that binds the E1 replication factor.

E2 Regulatory Proteins

The papillomavirus E2 proteins have well-characterized regulatory functions affecting viral transcription, viral DNA replication, and long-term plasmid maintenance. E2 was first described as a transcriptional activator⁵⁷² capable of activating viral transcription through E2 responsive elements located within the

viral genome.⁵⁷¹ The E2 proteins are relatively well conserved among the papillomaviruses in two domains: a sequence-specific DNA-binding and dimerization domain located in the carboxy terminal region of the protein and a transactivating domain that is located within the amino terminal half of the protein.^{211,398} These two domains are separated by an internal hinge region that is not well conserved in size or in amino acid composition among different papillomaviruses. The E2 proteins bind the consensus sequence, ACCN₆GGT,^{9,362} and can regulate transcription from promoters containing E2 binding sites.^{242,251,570} E2 binds ACCN₆GGT motifs as a dimer; the DNA binding dimerization domain localizes to the carboxy terminus of E2.³⁹⁹

The E2 proteins have been best studied in the BPV system, where three species have been identified (Fig. 54.9). The full-length protein (E2TA) can function as a transactivator or a repressor depending on the location of the E2-binding sites within the enhancer/promoter region. The two shorter forms of E2 called E2TR and E8/E2 have been described as repressors because they can inhibit the transactivation function of the full-length E2TA.^{344,345} The shorter E2 proteins contain the DNA binding and dimerization domains of the C terminus but lack the transactivation domain. E2TR and E8/E2 can inhibit the transcriptional transactivating function of the full-length polypeptide by competing for its cognate DNA binding sites and by forming inactive heterodimers with the full-length transactivator protein. The crystal structure of the

FIGURE 54.9. Structure of the BPV1 E2 gene products. The structures of the three known proteins encoded by the BPV1 E2 ORF are indicated. The 48-kD full-length E2 transactivator can be expressed from an unspliced message from P₂₄₄₃ or from a spliced messenger RNA (mRNA) from upstream promoters by utilizing a splice acceptor at nt 2558. The 31-kD and 28-kD forms of the repressor are expressed from P₃₀₈₀ and as an E8/E2 fusion by a spliced mRNA as shown, respectively. The transactivation domain consists of a region of approximately 200 amino acids at the N-terminal region of the full-length E2 protein that is relatively well conserved among papillomaviruses. This region, which is acidic and is predicted to contain amphipathic helices, is only present in the full length form of E2. The N-terminus of E2 contains the site for binding E1. The 110 C-terminal amino acids are also conserved and comprise the DNA-binding and dimerization domain. The basic region and the hydrophobic repeats are indicated.⁴⁰⁰

dimeric DNA-binding domain of BPV1 E2 revealed a previously unobserved structure for a DNA-binding protein, which is a dimeric antiparallel β barrel.²⁴⁶ The crystal structure of the N-terminal transactivation domain has also been resolved for HPV16 and HPV18.^{14,240} The structural studies of the E2 N-terminal domain indicated that it could form a dimer both in the crystal and in solution. Because amino acids that are necessary for transactivation are located at the dimer interface, the dimer structure may be important in the interactions of E2 with viral and cellular transcription factors. The dimer formation may contribute to the stabilization of DNA loops, which may serve to relocate distal DNA-binding transcription factors to the site of human papillomavirus transcription initiation.¹⁴

Mutations in the BPV1 E2 ORF have pleiotropic effects, disrupting transformation, replication, and transcriptional functions. Studies have shown that expression of the early region viral genes is under the control of the viral E2 gene product through E2 responsive elements located within the viral LCR. The actual role of the E2 transactivation function in the PV life cycle remains to be elucidated, however. Studies with an HPV31 genome that carried a mutant E2 gene that was defective for transactivation but competent for DNA replication competent could still be established as a stable episome and could induce differentiation-dependent late functions.⁵⁸⁹

E2 transcriptional regulation has also been well studied for the genital tract-associated HPVs. The binding of E2 to its cognate sites within the LCR of the HPV genomes results in the modulation of viral promoter activity. The E6 and E7 transforming genes of HPV16 and HPV18 are transcribed from the major early promoter (P₉₇ and P₁₀₅, respectively) contained

within the LCR of their respective genomes. In human epithelial cells, the HPV16 P₉₇ promoter and the HPV18 P₁₀₅ promoter display basal activities that can be repressed by full-length E2.^{37,506,608,609} There are four E2-binding sites upstream of the P₉₇ and P₁₀₅ promoters that mediate this repression. In addition to binding at its cognate sites, the E2 transcriptional activation function is required for E2-mediated promoter repression. Specific conservative point mutations within the bovine or human E2 transactivation domain that eliminate E2-mediated transcriptional activation also eliminate E6/E7 promoter repression.^{219,436} The bromodomain containing protein 4 (Brd4) is involved in this transcriptional repression.⁶⁷⁷ An unbiased whole genome small interfering RNA (siRNA) screen validated the involvement of Brd4 in this transcriptional repression and also revealed independent roles for the histone demethylase known as SMCX as well as components of the TIP60 histone acetylase complex including EP400.⁵⁶⁰

E2 can suppress the growth of HPV-positive cervical cancer cell lines through the transcriptional repression of the viral E6 and E7 genes.^{156,188,269,436,609} This repression results in the reactivation of the Rb and p53 tumor suppressor pathways that are inhibited by E6 and E7 and induce a cell cycle arrest and cellular senescence.^{217,218,649}

E2 is a multifunctional protein. Its functions as a transcriptional activator and repressor are likely mediated by interactions with specific cellular factors, some of which have now been identified (Table 54.1). In addition to its role as a transcriptional regulator, E2 has critical role in viral DNA replication. The full-length E2 proteins are critical auxiliary factors for viral DNA replication.^{103,137,623} This aspect has been

TABLE 54.1 Cellular Targets and Functions of the Papillomavirus E2 Regulatory Proteins

Associated cellular proteins	Functional consequences	References
Bromodomain protein 4	Tethers E2 and DNA to mitotic chromosomes	(688)
	Mediates transcriptional activation function	(539)
	Mediates transcriptional repression	(560,677)

best studied in the BPV system, where E2 was first shown to complex with E1 and to strengthen the affinity of E1 for binding to the origin of DNA replication.^{416,623}

E2 is also required for long-term episomal maintenance of viral genomes within replicating cells.^{27,273,357,475,556} The critical role of E2 in viral DNA replication is not sufficient to support long-term maintenance of the viral genomes. Genome maintenance requires, in addition, *cis* minichromosome maintenance elements consisting of multiple E2 binding sites.⁴⁷⁵ In the presence of E2, plasmids containing viral E2 binding sites associate with mitotic chromosomes. Furthermore, the chromatin attachment function correlates perfectly with the stable episomal maintenance of the viral plasmids.²⁷³ E2 facilitates viral genome segregation by interacting simultaneously with condensed mitotic chromatin and viral genomes, linking the viral plasmids to the cellular mitotic chromosomes, and thereby ensuring the viral genomes are contained within the nuclear envelope when it reforms during telophase. The TA domain is required for the association of E2 with mitotic chromosomes and for the genome maintenance function in dividing cells. Specific mutations in the TA domain have been shown to disrupt the tethering of viral genomes to mitotic chromosomes.^{2,28,693} The cellular protein Brd4 mediates the association of BPV-1 E2 to mitotic chromosomes and may play an important role for some other PVs.⁶⁸⁸ Furthermore the binding of E2 to Brd4 is conserved among all the papillomaviruses.^{274,339,688}

Additional cellular factors are likely to be involved in E2-mediated tethering to mitotic chromosomes and PV genome maintenance. For instance ChlR1 has been shown to be important for loading E2 onto mitotic chromosome.⁴⁵³ The E2 proteins of some of the alpha genus HPV types (HPV11, HPV16, and HPV18) have been shown to associate with the mitotic spindle rather than the chromosomes.⁶²⁹ It has been proposed that an association between mitotic spindles and these HPV E2 proteins might provide a mechanism for HPV viral genome persistence in host cells. Finally HPV8 E2 binds as large speckles at the ribosomal DNA loci at the pericentro-

meric regions of chromosomes.⁴⁸⁰ Therefore, different papillomavirus E2 proteins use different mechanisms to ensure the stable maintenance of their genomes in host cells and evaluation of these differences is likely to be fruitful.

The interaction of E2 with Brd4 is required for the transcriptional activation function of E2.⁵³⁹ Amino acid residues in the E2 TA domain required for Brd4 binding are also required for transcriptional activation, and siRNA knockdown of Brd4 protein levels reveals a role for Brd4 in E2 transcriptional activation.⁵³⁹ Brd4 is a member of the bromo and extra terminal (BET) family, a group of structurally related proteins characterized by the presence of two bromodomains and one extraterminal (ET) domain of unknown function.¹⁴¹ Bromodomains in general have been shown to interact with acetylated lysines in histones and are involved in chromatin targeting and remodeling.⁶⁷⁶ Unlike other bromodomain proteins, which are released from chromatin during mitosis, BET family members remain bound to chromatin during mitosis. Brd4 has been shown to influence the general RNA polymerase II-dependent transcription machinery by interacting with the core factors of the positive transcription elongation factor b (P-TEFb).^{281,684}

Late Gene Expression

The viral late functions, such as vegetative viral DNA synthesis, capsid protein synthesis, and virion assembly, occur exclusively in differentiated keratinocytes. Transcriptional regulation of the late genes is directed from a specific promoter that becomes active only in terminally differentiated keratinocytes. The late genes include the capsid genes L1 and L2, as well as E4, which is located in the early region of the viral genomes. Of interest the late promoters for the human papillomaviruses that have been analyzed do not map to the LCR. Instead, a differentiation-specific promoter (referred to as P₇₄₂ in HPV31 and P₆₇₀ in HPV16) has been identified within the E7 coding region which gives rise to mRNAs that map heterogeneously over a 100-bp region in the E7 gene.^{221,266} Keratinocyte differentiation by itself is able to activate low levels of late transcription, and genome

amplification also increases the level of late gene expression.^{48,574} Recent studies have also established differentiation changes in the levels of the CCAAT/enhancer binding protein (C/EBP), β repressors and activators in the regulation of the HPV late promoter.²³⁰

Papillomavirus L1 and L2 gene expression is also regulated at a posttranscriptional level. Cis elements have been described for BPV1 as well as several HPV types that regulate late gene expression at a posttranscriptional level. In the 3' untranslated regions (UTRs) of the late RNAs of each of these viruses there are negative regulatory elements that can inhibit the stability of late messenger RNAs. A negative regulatory element in the HPV16 3' UTR contains multiple 5' splice-like sequences, as well as an inhibitory GU-rich region that reduces mRNA stability and binds to specific cellular factors.^{142,305,322} Three different cellular factors (the U2 auxiliary splicing factor 65-kD subunit, the cleavage stimulation factor 64-kD subunit, and the Elav-like HuR protein) interact with the RNA and regulate its levels at a post-transcriptional level.³²² In HPV1, an AU-rich inhibitory region has been identified in the 3' UTR that also binds the Elav-like HuR protein.⁵⁶⁸ The model emerges that these, and perhaps additional cellular factors, are responsible for the nuclear retention or cytoplasmic instability of the nuclear retention element (NRE)-containing late transcripts. Keratinocyte differentiation would then lead to changes in these cell-encoded factors, thereby relieving the inhibition of late mRNA processing.

Virion Assembly and Release

Virion assembly takes place in the nuclei of terminally differentiated keratinocytes in which vegetative viral genome replication and expression of the virion proteins has occurred.¹⁵² Nuclear entry of L1 and L2 is mediated by cellular karyopherins, particularly the Kap alpha2/beta1 heterodimer.^{174,408} In addition to nuclear transport, karyopherin binding may prevent premature L1 assembly in the cytoplasm.⁴³ As noted above, L1 can assemble into VLPs. However, L2 may increase the efficiency of the assembly reaction.^{313,694} Hsc70 may also participate in the assembly reaction, since it is found in association with nuclear L2 but is displaced in L1/L2 capsids that have packaged DNA.¹⁸⁴ Packaging of the viral genome by the capsid proteins does not appear to require a sequence-specific packaging signal because many bacterial plasmids with no PV sequences can be efficiently packaged, at least in cultured cells, provided they are less than 8 kb in length.⁷⁴ Preferential encapsidation of the viral genome may involve a size discrimination mechanism. Nascent capsids might randomly coalesce around any nuclear DNA but would generally form unstable open structures. A stable closed structure could assemble only if the DNA molecule is approximately the size of the 8-kb viral genome. Consistent with this hypothesis, linear fragments of cellular DNA less than 8 kb in length are efficiently encapsidated if the nuclei of L1/L2 expressing cells are gently lysed and exposed to a double-stranded DNA endonuclease.⁷⁵ In cell culture systems, the L2 dependence for DNA encapsidation varies by PV type. For example, almost no DNA is encapsidated when BPV1 L1 is expressed alone, whereas HPV16 L1 alone rather efficiently encapsidates pseudoviral genomes or linear cellular DNA fragments, although the resulting DNA-containing L1-only capsids are essentially noninfectious.⁷⁵

Upon exposure to an oxidizing environment, as occurs in the upper layers of a terminally differentiated squamous epi-

thelium,¹¹⁴ the capsids are further stabilized by the formation of disulfide bonds between conserved cysteines on adjacent L1 monomers. This maturation process condenses the capsid and increases its regularity and resistance to proteolytic digestion.⁷⁵ Formation of disulfide-linked L1 dimers and trimers was observed after capsid production in replicating cultured cells or *in vitro* raft cultures.^{75,115} Neither L2 nor encapsidated DNA appreciably influences the formation of L1 disulfide bonds. However, the extent of cross-linking varies by PV type, for example, being much greater for BPV1 than HPV16.^{75,668} PVs are not believed to be cytolytic, and release of the virions is thought to occur as a result of the normal loss of nuclear and cytoplasmic membrane integrity during terminal differentiation of the infected keratinocyte. E4-mediated collapse of cytokeratin filaments might assist in virion release.¹⁵³

Viral DNA Replication

Little is known about the initial stages of viral DNA replication and amplification that occur following infection of a basal keratinocyte, when there is an amplification of the viral genome to approximately 50 to 100 copies. In cells in which the viral DNA has been established, the viral DNA is maintained as a stable multicopy plasmid. The viral genomes replicate an average of once per cell cycle during S-phase in synchrony with the host cell chromosome.²⁰⁷ As a multicopy plasmid, this type of DNA replication ensures a persistent infection in the basal cells of the epidermis. Vegetative DNA replication occurs in the more differentiated epithelial cells of the papilloma. Such differentiated cells have exited the cell cycle and are no longer capable of supporting cellular DNA synthesis. Through E6 and E7, however, the HPVs activate the DNA replication machinery to support vegetative viral DNA synthesis producing the genomes to be packaged into progeny virions.

Origin of DNA Replication

Papillomavirus DNA replication requires the origin of DNA replication in *cis* and the viral E1 and E2 proteins in *trans*. The minimal origin of DNA replication contains an A+T rich region (ATR), the E1 binding site that includes a region of dyad symmetry (DSR), and an E2 binding site.⁶²⁴ Origin-dependent DNA replication can be achieved *in vitro* with cell extracts containing high levels of E1 alone in the absence of E2.^{543,681} E1 is the essential virus-encoded replication factor and functions as an ATP-dependent helicase. The role of E2 is as an auxiliary factor in viral DNA replication; the binding of E1 to the origin of replication is stabilized through its interaction with E2 and the binding of E2 to its cognate sites adjacent to the origin.^{416,624}

The E1 Protein

The E1 protein is highly conserved among the PVs, and the BPV1 E1 protein is a 68-kD nuclear phosphoprotein that binds specifically to the origin of replication.^{616,624,664} By itself, E1 binds the origin with weak affinity; however, this binding is stabilized through its interaction with E2. E1 has DNA-dependent ATPase and DNA helicase activities.^{65,543,682} E1 is required for both the initiation and elongation of viral DNA synthesis.³⁶⁸ In addition to its interaction with E2, E1 has been shown to bind a number of cellular proteins. E1 interacts with the p180 subunit of the cellular DNA polymerase α -primase and thereby recruits the cellular DNA replication initiation machinery to the viral replication origin.^{52,457} Several additional host

cellular proteins have been found to bind E1, including histone H1,⁵⁹⁶ SW1/SNF5,³⁵⁴ cyclin E/Cdk2,^{121,385} Hsp40/Hsp70,³⁶⁹ and Ubc9.^{492,685} Although the physiologic significance of some of these interactions remains to be determined, several appear to be quite interesting. In particular, the efficient cell cycle-regulated replication of papillomavirus genomes is dependent upon the association of E1 with the S-phase specific cyclin E-Cdk2 complex.¹²¹ In addition, the interaction of E1 with Ubc9 is required for efficient origin-dependent replication.⁶⁸⁵ E1 is small ubiquitin-like modifier 1 (SUMO-1) modified by Ubc-9, and this modification is required for the intranuclear accumulation of E1.⁴⁹³

E2 Protein Replication Functions

Papillomavirus DNA replication requires E2 as an auxiliary factor.^{623,681} Although not essential for origin-dependent DNA replication *in vitro*, E2 greatly stimulates the ability of E1 to initiate DNA replication.⁶⁸¹ E2 interacts with E1^{46,383,416} and greatly enhances the ability of E1 to bind the replication origin.^{416,541,544} E2 can relieve nucleosome mediated repression of papillomavirus DNA replication *in vitro*.³⁶¹ The E1–E2 complex is a precursor to a larger multimeric E1 complex, which after the removal of E2 can distort the replication origin and ultimately unwind the DNA (Fig. 54.10).³⁸⁴ E2 serves as an auxiliary factor that fosters the assembly of the preinitiation complex at the origin, but E2 itself plays no intrinsic role in viral DNA replication. A hexameric form of E1 protein is associated with the ATPase and DNA helicase activities intrinsic to its initiator function in DNA replication.^{186,542}

Vegetative Viral DNA Replication

Vegetative replication of papillomavirus DNA is necessary to generate the genomes to be packaged in virions, a process that normally occurs only in the terminally differentiated epithelial cells of a papilloma. The mechanisms regulating the switch from plasmid maintenance to vegetative viral DNA replication are not known. The switch may involve the presence or absence of controlling cellular factors in differentiating keratinocytes. In addition, or alternatively, the relative levels of viral factors such as E1 or E2 (or their modification) may change in terminally differentiating keratinocytes. There have been few studies that have examined the mode of vegetative viral DNA replication in differentiated cells. One might anticipate that, as with the polyomaviruses, vegetative DNA replication occurs bidirectionally through theta structure intermediates, as it does in the maintenance replication phase. One intriguing study, however, suggests that there may be a switch from a bidirectional mode of replication to what could be a rolling circle mode.¹⁸² Additional studies on the mechanism of vegetative replication would appear to be warranted.

VIRAL TRANSFORMATION

BPV-1 Transformation

Certain papillomaviruses are capable of inducing cellular transformation in tissue culture. The best studied of the transforming papillomaviruses is BPV1. Morphologic transformation in tissue culture was first described for BPV in the early 1960s.^{45,50,612} In the late 1970s, a focus assay was developed using established cell lines to study BPV1 transformation.¹⁶³ In general, investigators have relied upon mouse C127 cells and NIH 3T3 cells for these transformation studies, although a

FIGURE 54.10. Proposed pathway for the assembly of an initiation-competent complex at the bovine papillomavirus (BPV) origin of DNA replication. The E1 initiator binds cooperatively with E2 to the ori forming a specific E1₂E2₂–DNA complex. As a consequence of the interaction between the E1 and E2 DNA binding domains (DBDs), a sharp bend is induced in the ori DNA. The bend promotes the interaction between the E1 helicase domain (E1H) and the E2 transactivation domain (E2AD). The resulting highly sequence-specific complex serves to recognize the ori. In a reaction requiring ATP hydrolysis, E2 is displaced and additional E1 molecules are added to the complex, resulting in the formation of a complex where four molecules of E1 are bound to the ori. This complex can distort the DNA duplex to and give rise to partially single-stranded regions. Subsequently, additional molecules are added. In a final step, E1 is assembled onto the exposed single strands forming a hexameric ring-like structure that constitutes the replicative helicase. (Courtesy of Arne Stenlund; modified from Enemark E, Chen G, Vaughn DE, et al. Crystal structure of the DNA binding domain of the replication initiation protein E1 from papillomavirus. *Molec Cell* 2000;6:149–158.)

variety of other rodent cells, including hamster and rat cells, are susceptible to BPV1-mediated transformation. Transformation of mouse C127 cells by BPV1 causes alterations in morphology, loss of contact inhibition, anchorage independence, and tumorigenicity in nude mice.¹⁶³

One notable characteristic of BPV1 transformed rodent cells is that the viral DNA is maintained as a stable multicopy plasmid.³⁴⁹ Integration of the viral genome is not required for either the initiation or maintenance of the transformed state. However, transformation is dependent upon the continued expression of viral genes as evidenced by the loss of the transformed phenotype in mouse cells that have been “cured” of the viral DNA by treatment with interferon.⁶²²

Genetic studies mapped the BPV1 transforming genes to the E5, E6, and E7 ORFs. The E5 gene is the major transforming gene of BPV1 in transformed cells. E5 encodes a small (44 amino acid) integral membrane protein that is sufficient for the transformation of certain established rodent cells in culture, and does so by activating the platelet derived growth factor (PDGF) β receptor to transform cells in a ligand-independent manner.^{467,468} The molecular biology of BPV1 E5 and its mechanism of transformation are described in more detail in Chapter 7. E5 is highly conserved among the group of papillomaviruses that induce fibropapillomas in their natural host and have the capacity to induce fibroblastic tumors in hamsters. The E5 gene is believed to be responsible for the proliferation of dermal fibroblasts in fibropapillomas.

The E6 and E7 genes of all the papillomaviruses encode proteins with conserved structural motifs. They contain domains of almost identically spaced CYS-X-X-CYS motifs (four in E6 and two in the carboxy-terminal portion of E7). It has been postulated that the E6 and E7 genes may have arisen from duplication events involving a 39-codon core sequence containing one of these motifs.¹¹² The CYS-X-X-CYS motifs found in a number of nucleic acid binding proteins are characteristic of zinc-binding proteins. The papillomavirus E6 and E7 proteins bind zinc through these cysteine residues.^{24,225} BPV1 E6 and E7 have not been studied as extensively as their HPV counterparts, and they appear to transform through p53- and pRB1-independent mechanisms. As such, studies on the mechanisms by which BPV1 E6 and E7 transform cells could provide insights into the p53 and pRB independent activities of the HPV E6 and E7 oncoproteins, discussed in detail below.

HPV Immortalization and Transformation

The HPV16 and HPV18 genomes are not as efficient as BPV1 DNA at inducing transformation of established rodent cells; however, transformation can be achieved when the HPV DNA is transfected along with a second selective marker, such as the neomycin resistance gene.⁶⁸⁶ Immortalization assays employing primary rodent cells, primary human fibroblasts, and/or primary human keratinocytes have proven more informative. In such assays, the high-risk HPVs, such as HPV16 and HPV18, are positive for immortalization or transformation, whereas the low-risk viruses, such as HPV6 and HPV11, are not.^{535,585} These assays permitted the mapping of the E6 and E7 as oncogenes for the high-risk HPV types.

In established rodent cells, such as the NIH3T3 cells, the E7 ORF scores as the major HPV transforming gene.^{471,605,640,647,687} HPV16 and HPV18 by themselves are not able to transform primary rat fibroblasts or baby rat kidney cells.^{343,471} However, the E7 gene can cooperate with an activated *ras* oncogene to fully transform primary rat cells.^{30,362,440,471,585}

The DNAs of the high-risk HPVs can also be distinguished from the DNAs of the low-risk HPVs by their abilities to immortalize primary human fibroblasts, human foreskin keratinocytes, or human cervical epithelial cells.^{161,476,535,646,673} The resulting cell lines are neither anchorage-dependent nor tumorigenic in nude mice, but they do display altered growth properties and are resistant in the response to signals for terminal differentiation.^{161,302,476,535}

HPV E6

The HPV E6 proteins are approximately 150 amino acids in size and contain four Cys-X-X-Cys motifs that are involved

in binding zinc.^{24,225,226} The first transforming activity identified for the high-risk alpha genus HPV E6 proteins (such as HPV16 and HPV18) was the ability complement E7 in the immortalization of human keratinocytes.^{245,421} This activity was soon explained by its ability to complex p53,⁶⁵⁵ a property not possessed by the low-risk HPV E6 proteins. Through its interaction with p53, E6 blocks the transcriptional function of p53 to activate p53-responsive promoters.⁴¹² The protein levels of p53 are generally quite low in HPV-positive carcinoma cell lines and in cells immortalized by the HPV oncoproteins,⁵²³ due to the ability of the E6 proteins of high-risk HPV types to promote the ubiquitin-dependent degradation of p53.⁵²⁵ Expression of the high-risk E7 proteins and their engagement of the pRB family of proteins results in an increase in the levels of p53 within cells, which in turn transcriptionally activates the expression of cell cycle arrest genes or proapoptotic genes.²⁸⁷ Indeed the half-life of p53 is dramatically decreased in E6-expressing cells, and E6 prevents the increase in p53 levels when cells are challenged with genotoxic agents.^{260,523} In targeting p53, the high-risk HPV E6 proteins inhibit DNA damage and oncogene-mediated cell death signals.^{167,287,308} Therefore, like SV40 Tag and Ad E1B that also target p53, HPV E6 has antiapoptotic activities and can interfere with the cell cycle regulatory functions of p53. E6 also can induce genomic instability, as evidenced by the development of translocations and aneuploidy in culture,^{498,657} as well as maintenance of stable episomal replication during the viral life cycle,⁴⁵⁸ and immortalization of human mammary epithelial cells.^{23,549}

HPV16 E6 induces p53 degradation by forming a complex with the cellular ubiquitin-protein ligase E6AP,^{263,264} which is then able to bind and ubiquitylate p53.⁵²² E6AP is the founding member of a class of ubiquitin-protein ligases called HECT E3 proteins, which directly transfer ubiquitin to their substrates.⁵²⁴ The catalytic domain of HECT proteins is a conserved 350 amino acid region defined by its homology to the E6AP carboxy terminus (HECT).²⁶² The HECT domain binds to specific E2 enzymes and contains an active site cysteine residue that forms a thioester bond with ubiquitin.^{262,524} (Fig. 54.11). Structure studies have determined that the HECT domain is a bilobed structure, with a larger N-terminal lobe that interacts with the ubiquitin-conjugating enzyme, and a smaller C-terminal lobe containing the catalytic cysteine residue.²⁵⁷

Levels of p53 in E6-immortalized cells or in HPV-positive cervical carcinoma cells are, on average, two- to threefold lower compared to primary cells.⁵²³ In uninfected cells, intracellular p53 levels increase significantly in response to DNA damage or genotoxic stress.²⁹⁹ The higher levels of p53 can result in a G₁ growth arrest or apoptosis, as part of a cell defense mechanism that allows for either the DNA damage to be repaired prior to the initiation of a new round of DNA replication or the removal of the cell. E6-expressing cells, however, do not manifest a p53-mediated cellular response to DNA damage,³⁰⁸ indicating the ability of E6 to promote the degradation of p53 and prevent the steady level of p53 to rise above a certain threshold level (Fig. 54.12). Under DNA-damaging conditions, the E6-stimulated degradation of p53 abrogates the negative growth regulatory effect of p53, and as such contributes to genomic instability. E6AP does not normally regulate p53 ubiquitylation in the absence of E6. In binding E6AP, E6 directs E6AP to p53 allowing it to form a ternary complex. It should be noted that E6AP does not regulate p53 protein

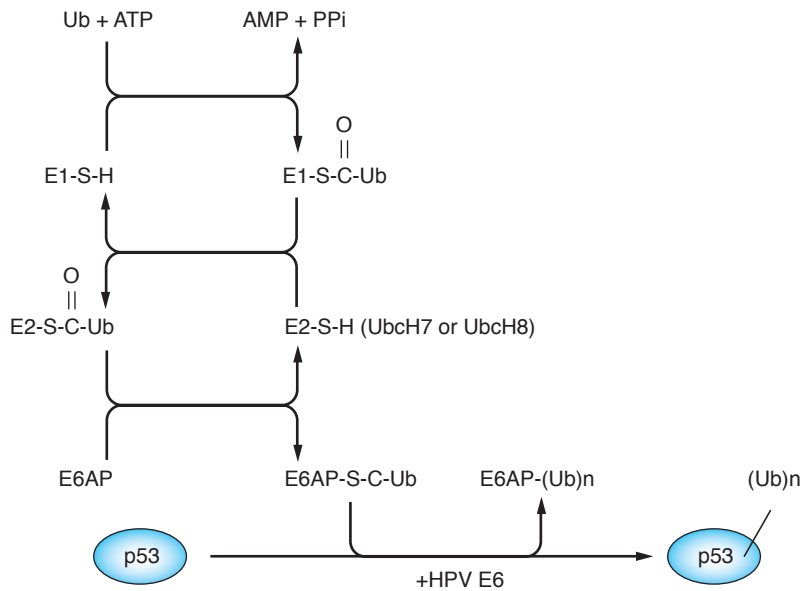

FIGURE 54.11. A ubiquitin thioester cascade model for the human papillomavirus (HPV) E6 dependent ubiquitination of p53. The E6 protein binds to the cellular protein E6AP, and the complex together functions as an E3 (ubiquitin protein ligase) in facilitating the ubiquitination of p53.⁵²² The ubiquitination of a protein involves three cellular activities: E1 (ubiquitin activating enzyme), E2 (ubiquitin conjugating enzyme), and E3 (ubiquitin protein ligase). Ubiquitin is activated in an ATP-dependent manner and forms a high energy thioester with E1, which can then be transferred to the E2 through a thioester linkage. Ubiquitin can then be transferred to a cysteine within the Hect domain of E6AP, again as a thioester linkage⁵²⁴ through the direct binding of E6AP with UbcH7 or UbcH8.³³⁷ In conjunction with HPV-16 E6, E6AP then recognizes p53 and catalyzes the formation of an isopeptide bond between the carboxy-terminal glycine of ubiquitin and a lysine side chain of p53. In catalyzing the ubiquitination of p53, HPV-16 E6 also induces the self-ubiquitination and proteolysis of E6AP.²⁹⁵

stability in non-E6-expressing cells^{31,602}; the ubiquitin ligase MDM2 is the major E3 ubiquitin ligase responsible for p53 degradation in the absence of E6.^{244,334}

The HPV16 E6 protein binds to E6AP within the N-terminal substrate recognition domain, directing E6AP to ubiquitylate p53.²⁶⁵ The E6AP protein is encoded by the UBE3A gene that is located in an imprinted region on chromosome 15q11-q13, and it has been linked to Angelman's syndrome, a neurogenetic disorder characterized by severe mental retardation, ataxia, loss of speech, seizures, and other abnormalities.^{314,396} Several potential E6-independent substrates of E6AP have now been identified, including the human homolog of the yeast RAD23 protein involved in nucleotide excision repair (HHR23A), the src-family kinase Blk, and the MCM7 subunit of replication licensing factor.^{335,338,442} In addition, E6 induces self-ubiquitylation of E6AP.²⁹⁵ It is conceivable that the redirection of E6AP activity toward p53 by E6 might affect (either enhance or inhibit)

the targeting of the normal substrates of E6AP, and that such an alteration of E6AP activity could account for some of the transforming activity of E6. E6AP is a component of a number of cellular complexes, including the proteasome and a 2MDa complex that contains Herc2 and Neurl4.³⁹³ E6 is recruited to each of these complexes by E6AP. E6 encodes a number of p53-independent functions that are relevant to cellular transformation and immortalization, and there are HPV16 E6 mutations that separate p53 degradation from cellular immortalization.^{315,372} It is possible that some of the p53-independent activities of E6 are still mediated by E6AP through the activities of these other cellular complexes.

A number of additional cellular targets have been identified for the high-risk alpha genus HPV E6 proteins (Table 54.2). Of note, the high-risk E6 oncoproteins contain an X-(S/T)-X-(V/I/L)-COOH motif at the extreme C-terminus that mediates binding with cellular PDZ domain-containing proteins. This motif

FIGURE 54.12. The level of p53 in primary cells is generally low. DNA damaging agents, viral infection, and expression of E7 increase the level of p53. Elevated levels of p53 can lead to either apoptosis or a cell-cycle checkpoint arrest in G1 through the transcriptional activation of proapoptotic genes or p21^{cip1}. Viral oncoproteins may interfere with this negative growth regulatory function of p53, either by sequestering p53 into a stable, but nonfunctional complex (such as with SV40 TAg or the Ad5 55 kD E1B protein), or by ubiquitylation and enhanced proteolysis as observed with the high risk human papillomavirus (HPV) E6 proteins.

TABLE 54.2 Cellular Targets of the Papillomavirus E6 Oncoproteins

Associated cellular proteins	Functional consequences	References
E6-associated protein (E6AP) (Alpha genus HPVs)	Ubiquitylation and proteolysis of associated proteins	(522)
Mastermind-like 1 (MAML1) (Cutaneous PVs)	Ubiquitylation of E6	(295)
p53	Repress Notch transcription and signaling	(70,603)
Reticulocalbin 2 (Erc55 or E6BP)	E6AP dependent ubiquitylation and proteolysis	(525,655)
Paxillin	Unknown	(98)
PDZ domain-containing proteins: HDlg, MUPP1 and hScrib (HR HPVs only)	Disruption of the actin cytoskeleton	(619,631)
Interferon regulatory factor 3 (IRF-3); Clathrin adaptor complex AP-1	E6AP dependent ubiquitination and proteolysis	(197,356,427)
Bak	Inhibition of β -interferon induction	(510)
CBP/p300	Unknown	(618)
Myc	Inhibition of Bak induced apoptosis	(611)
NFX1-91	Inhibition of p53 transcriptional activity	(462,697)
E6 oncoprotein targeted protein 1 (E6TP-1)	Activation of cellular telomerase	(371)
ADA3	Activation of cellular telomerase	(205,206)
FADD/Caspase 8	E6 induced degradation	(196)
	Transcriptional regulation	(336)
	Block apoptosis	(180,198)

Gene abbreviations: Tumor suppressor protein 53 (p53); CREB-binding protein (CBP); Bcl2 antagonist killer (Bak); myelocytomatosis viral oncogene homolog (Myc); Nuclear factor, X-box binding (NFX1-91); Homolog of yeast putative transcriptional adaptor (ADA3); Fas-associated protein with death domain (FADD).

is unique in the high-risk HPV E6 proteins and is not present in the E6 proteins of the low-risk alpha genus HPV types. E6 serves as a molecular bridge between these PDZ domain proteins and E6AP, facilitating their ubiquitylation and mediating their proteolysis. Among the PDZ domain proteins implicated as E6 targets are hDlg, the human homolog of the *Drosophila melanogaster* discs large tumor suppressor, and hScrib, the human homolog of the *Drosophila* scribble tumor suppressor.^{197,427} Additional PDZ domain proteins shown to be capable of binding to E6 are the membrane associated guanylate kinase protein 1, 2 and 3 (MAGI 1, MAGI 2 and MAGI 3), the multi-PDZ domain protein (MUPP1) and the a cytoplasmic interacting protein containing a PDZ domain (TIP 2/GIPC).^{173,215,356,613} Several of the PDZ-containing proteins have been shown to be involved in negatively regulating cellular proliferation. Therefore some of the p53-independent transforming activities of the high-risk E6 oncoproteins may be linked to their ability to bind and degrade some of these PDZ motif-containing proteins.

An important p53-independent activity of HPV16 E6 is its ability to activate telomerase in keratinocytes,³²⁰ through the transcriptional upregulation of the rate-limiting catalytic subunit of human telomerase (hTERT).^{315,443,632} Maintenance of telomere length is an important step in cellular immortalization and transformation, which occurs either through transcriptional activation of hTERT expression or through the activation of the ALT recombination pathway. Activation of hTERT is observed in most human cancers, including HPV-positive cervical cancers. The mechanism of hTERT promoter activation by E6 is complex. It involves the c-Myc transcription factor that binds to the hTert promoter, and it involves the E6AP-dependent degradation of a transcriptional repressor of the hTERT promoter, NFX1-91.^{205,206} Interactions of E6 with E6AP as well as c-Myc have been shown to be important in the transcriptional activation of the hTERT promoter.^{370,371,633,679}

HPV16 E6 has also been reported to bind the transcriptional co-activator p300/CBP, a target also of Ad E1A and

SV40 large T antigen.^{462,697} This interaction is limited to E6 proteins of high-risk HPVs associated with cervical cancer that have the capacity to repress p53-dependent transcription. The repression of p53 transcriptional activity by targeting the p53 co-activator CBP/p300 provides a second mechanism which can inhibit p53. A subsequent study has shown that *in vitro*, E6 can inhibit p300-mediated acetylation on p53 and nucleosomal core histones.⁶¹⁴ A variety of other E6 cellular targets have been identified (Table 54.2); however, the physiologic relevance to transformation or immortalization has not yet been elucidated. It is possible that the binding of E6 to some of these targets might contribute to the virus-host cell functions unrelated to cellular transformation.

Other p53-independent activities for the alpha genus HPV E6 proteins have been described in the literature, including the activation of cap-dependent translation.⁵⁷³ Recent reviews that provide more detail on these activities have been published.^{256,403,418}

Most studies thus far on the molecular biology of the HPV E6 proteins have been on the alpha genus high-risk HPV types. Studies of the cutaneous HPVs are more limited, and less is known about the cellular activities of the cutaneous HPVs of the beta genus. Recently, the beta HPV E6 types as well as BPV1 E6 have been shown to bind Mastermind-like 1 (MAML1) and other members of the Notch transcription complex.^{70,603} MAML1 is a core component of the transcriptional activation complex that mediates the effects of the canonical Notch signaling pathway.⁶⁷⁵ BPV1 and beta-HPV E6 repress Notch transcriptional activation, and this repression is dependent on an interaction with MAML1. Furthermore, the expression levels of endogenous Notch target genes are repressed by beta-HPV E6 proteins.⁶⁰³

Notch-dependent transcriptional programs are critical in the differentiation and cell cycle arrest of keratinocytes.^{378,491} In addition, inactivating Notch pathway mutations have been recently reported in squamous cell carcinomas of the head and

FIGURE 54.13. Amino acid sequence similarity between portions of conserved regions 1 and 2 (CR1 and CR2) of the Ad5 E1A proteins and the amino terminal 38 amino acids of HPV16 E7. CR2 contains the pRB binding site and the casein kinase II (CKII) phosphorylation site of HPV16 E7.

neck,^{3,588} and the skin,⁶⁴³ consistent with the notion that Notch signaling is a tumor suppressor pathway in squamous epithelial cells.¹⁵⁵ E6 binding to MAML1 provides a novel mechanism of viral antagonism of HPV16 Notch signaling, and suggests that Notch signaling is an important epithelial cell pathway target for the beta-HPVs. Of interest, papillomavirus E6 proteins appear capable of binding to E6AP or to MAML1.

HPV E7

The E7 protein encoded by the “high risk” HPVs is a small protein of about 100 amino acids, has been shown to bind zinc, and is phosphorylated by casein kinase II (CK II).⁴⁰² E7 is a multifunctional protein that shares some functional similarities with adenovirus (Ad) 12S E1A.⁴⁷¹ The HPV proteins also share important amino acid sequence similarity with portions of the AdE1A proteins and the SV40 large tumor antigen (TAG) (Fig. 54.13). These conserved regions are critical for the transforming activities in all three viral oncoproteins, and have been shown to participate in the binding to a number

of important cellular regulatory proteins, including the product of the retinoblastoma tumor suppressor gene pRB, and the related pocket proteins, p107 and p130.^{135,165,659} Complex formation with pRB involves conserved region 2 of the Ad E1A protein and the corresponding region in the E7 protein and in SV40 large Tag.^{135,660}

The retinoblastoma protein is a member of a family of cellular proteins that also includes p107 and p130, which are homologous in their binding “pockets” for E7, AdE1A, and SV40 TAG. Its phosphorylation state is regulated through the cell cycle, being hypophosphorylated in G₀ and G₁ and phosphorylated during S, G₂, and M. pRB becomes phosphorylated at multiple serine residues by cyclin-dependent kinases at the G₁/S boundary and remains phosphorylated until late M, when it becomes hypophosphorylated again through the action of a specific phosphatase (Fig. 54.14). The hypophosphorylated form represents the active form with respect to its ability to inhibit cell cycle progression. HPV16 E7, like SV40 TAG, binds preferentially to the hypophosphorylated form of pRB, resulting

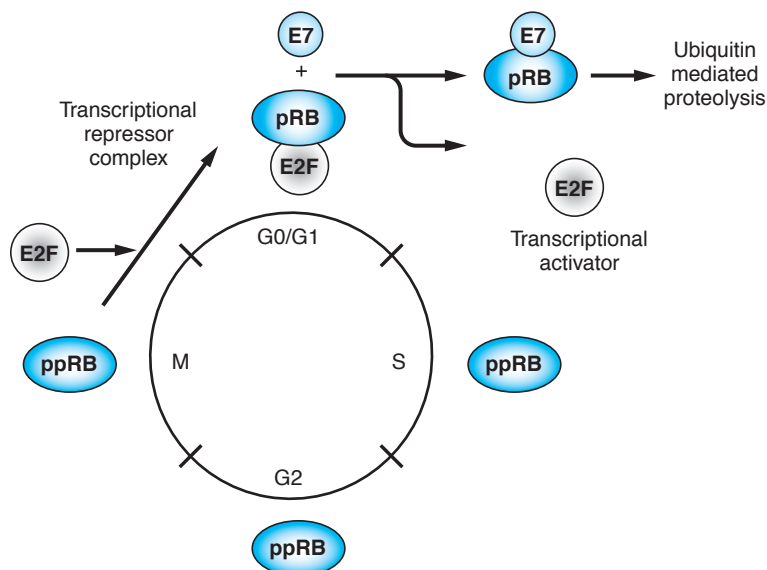

FIGURE 54.14. E7 abrogates the cell cycle regulation mediated by pRB (as well as the related proteins p107 and p130) by complex formation. During the cell cycle, pRB is differentially phosphorylated, and the underphosphorylated form is detected only in the G₀/G₁ phase. This underphosphorylated form is the active form of pRB, acting as a negative regulator of the cell cycle. During the transition to the S-phase, pRB is phosphorylated by cyclin-dependent kinases (cdk), resulting in the inactivation of its cell cycle regulatory functions. Members of the E2F family of cellular transcription factors are preferentially bound to the under-phosphorylated form of pRB, and in complex with pRB cannot activate transcription. Phosphorylation of pRB or complex formation with E7 results in the release of the E2F factors, allowing them to function as transcriptional activators of cellular genes involved in cellular DNA synthesis and progression into the S phase of the cell cycle.

TABLE 54.3 Cellular Targets of the Human Papillomavirus E7 Oncoproteins

Associated cellular proteins	Functional consequences	References
Retinoblastoma protein and related pocket proteins pRB, p107, p130	Disruption of E2F transcription factor complexes Degradation	(164,165) (61,287)

in the functional inactivation of pRB through the release of E2F transcription factors, thus permitting progression of the cell into S phase of the cell cycle. This property of the viral oncoproteins to complex pRB accounts, at least in part, for their ability to induce DNA synthesis and cellular proliferation. The high-risk HPV E7 proteins associate with the pocket proteins and induce their proteasomal degradation.^{61,287} The LXCXE motif within the CR2 homology domain of E7 is sufficient for pocket protein binding,^{166,422} but additional sequences located in the immediate amino terminal CR1 homology domain of E7 are required for pocket protein degradation,²⁸⁷ and these sequences are also necessary for the transforming activities of E7.⁴⁷⁰

E7 targeting the pocket proteins, including pRB, is not sufficient to account for its immortalization and transforming functions, indicating that there are likely to be additional cellular targets of E7 that are relevant to cellular transformation.²⁸³ Table 54.3 provides a list of various cellular targets with which E7 has been shown to bind. The physiologic relevance of many of these interactions is unclear.

Of particular interest are the reports that E7 can interact with cyclin-dependent kinase (cdk) inhibitors. As with E1A, HPV16 E7 interacts with and abrogates the inhibitory activity of p27^{kip1}.⁶⁸⁹ Because p27^{kip1} is involved in mediating cellular growth inhibition by transforming growth factor (TGF)- β in keratinocytes, this activity may contribute to the ability of E7 to override TGF- β -associated growth arrest.⁴⁷³ HPV16 E7 can also associate with p21^{cip1} and abrogate its inhibition of cdks as well as its inhibition of proliferating cell nuclear antigen (PCNA)-dependent DNA replication.^{194,286} p21^{cip1} is normally induced during keratinocyte differentiation,⁴¹⁵ and presumably its inhibition by E7 may be critical to allowing the replication of papillomavirus DNA in differentiated squamous epithelial cells.¹⁰¹

E7 is necessary for the stable maintenance of HPV episomes in epithelial cells,^{181,610} and sequences in E7 that contribute to cellular transformation are also important for the functions in the viral life cycle.^{373,610} Hence, the ability of E7 proteins to induce DNA replication through the release of E2F transcription factor

complexes and the inactivation of p21^{CIP1}^{194,286} and p27^{KIP1}⁶⁸⁹ is an essential component of the HPV replication strategy.

The high-risk HPV E7 proteins cause genomic instability in normal human cells.⁶⁵⁷ HPV16 E7 induces G1/S and mitotic cell cycle checkpoint defects and uncouples synthesis of centrosomes from the cell division cycle.⁴²⁰ This causes formation of abnormal multipolar mitoses, leading to chromosome mis-segregation and aneuploidy.¹⁵⁷ Moreover, there is an increased incidence of double-stranded DNA breaks and anaphase bridges, suggesting that in addition to numerical abnormalities, high-risk E7 proteins also induce structural chromosome aberrations.¹⁵⁸ Abnormal centrosome duplication rapidly results in genomic instability and aneuploidy, one of the hallmarks of a cancer cell. This activity is therefore likely to be functionally relevant to the contribution of high-risk HPV to malignant progression.

The HPV and BPV E7 proteins also bind to UBR4 (also known as p600).^{139,261} This binding appears to be conserved among all HPV E7 proteins (alpha as well as beta genera).⁶⁵⁸ The binding to p600 might therefore be important in mediating some of the pRB-independent functions of E7 such as modulating anoikis.¹³⁸ UBR4 may be involved in N-end rule ubiquitylation, but its cellular function remains to be determined.

The high-risk HPV E7 proteins have also been shown to reprogram cellular transcriptional programs. This has been reviewed recently.⁴⁰³ E7 binds to both canonical and noncanonical E2F family members^{270,402} and affects their transcriptional activities. E7 binds E2F6, a component of the polycomb repressive complex, and the detection of E2F6/polycomb repressive complexes is decreased in E7-expressing cells.⁴⁰²

The repressive H3K27 marks, which are necessary for binding of polycomb repressive complexes, are decreased in HPV16 E7-expressing cells due to the transcriptional induction of the KDM6A and KDM6B H3K27-specific demethylases.⁴⁰¹ HPV16 E7-mediated KDM6B induction accounts for expression of p16(INK4A).⁴⁰¹ Moreover, KDM6A- and KDM6B-responsive Homeobox genes are expressed at significantly

higher levels, indicating that HPV16 E7 results in reprogramming of host epithelial cells. These effects are independent of the ability of E7 to inhibit the retinoblastoma tumor suppressor protein.

What are the roles of the E6 and E7 oncoproteins in the normal life cycle of an HPV infection? It is likely that they function to allow the replication of the viral DNA. The viral E1 and E2 proteins are necessary for the initiation of viral DNA replication, but the virus is otherwise totally dependent on host cell factors, including DNA polymerase α , thymidine kinase, PCNA, and so on, for the replication of its DNA. These are proteins that are normally only expressed in S-phase during cellular DNA replication in cycling cells. Vegetative DNA replication for the papillomaviruses, however, occurs only in the more differentiated cells of the epithelium that are no longer cycling (see Fig. 54.5). Therefore, the papillomaviruses have evolved a mechanism similar to that of the polyomaviruses and the adenoviruses, to activate the cellular genes necessary for the replication of their own DNA in otherwise quiescent cells. These viruses may do so through the E7 proteins and their ability to release the E2F transcription factors by binding the pocket proteins including pRB (Fig. 54.13). In addition, E7 binds and inhibits the cdk inhibitor p21^{cip1} that is normally induced during keratinocyte differentiation, again presumably for the purpose of permitting viral DNA replication in a differentiated cell. The high-risk HPV E7 proteins, when expressed in the absence of E6, result in increased levels of p53 and in either a G1-mediated cell cycle arrest or apoptosis, depending upon the cell type. The mechanistic link between the pRB and p53 pathways is discussed in Chapter 7. E7 creates a signal that increases p53 levels. E6, by promoting the degradation of p53, counters this activity of E7 and permits the E7-dependent activation of the cellular DNA replication genes required for viral DNA replication.

HPV E5

Many of the papillomaviruses that induce purely epithelial papillomas (such as CRPV and the HPVs) contain E5 genes with the potential to encode short hydrophobic peptides. The structural similarity of these peptides to the BPV1 E5 protein has prompted studies of the potential transforming activities of the HPV E5 genes. The E5 proteins of the HPVs are required for optimal growth.^{175,201} In tissue culture, various HPV E5 genes have been shown to have some modest transforming activities, and in transgenic mice HPV16 E5 expressed in basal keratinocytes can alter the growth and differentiation of stratified epithelia and induce epithelial tumors at a high frequency.²⁰²

Although the biochemical mechanisms by which the E5 genes of the epitheliotropic papillomaviruses exert their growth stimulatory effects have not yet been fully elaborated, they may involve interactions with the epidermal growth factor receptor (EGFR) or the 16-kD subunit of the vacuolar ATPase, each of which has been shown to bind HPV E5 proteins.^{113,202,268,586,587,691} As with the BPV1 E5 protein, HPV16 E5 can bind the 16-kD subunit of the vacuolar ATPase and can inhibit the acidification of endosomes.^{113,502,586} It should be noted, however, that the E5 gene is not expressed in most HPV-positive cancers, suggesting that if the E5 gene does stimulate cell proliferation *in vivo*, it presumably functions in benign papillomas and not in the cancers. It might also par-

ticipate in the initiation of the carcinogenic process or in some other aspects of the viral–host cell interaction relevant to the pathogenesis of the HPV infection. Indeed there are some data that would implicate E5 in the down-regulation of major histocompatibility complex (MHC) class II antigen expression.⁶⁹⁰

Propagation and Assay in Cell Culture

PVs have proved difficult to propagate *in vitro* because these viruses replicate in stratified squamous epithelium, which is not mimicked in monolayer cultures. Most clinical identifications of PV infection, therefore, rely on a technique that identifies the viral DNA, such as polymerase chain reaction (PCR) or a molecular hybridization technique, rather than on virus replication in culture.

Although the species specificity of PV has also limited the utility of animals for the study of HPV, an early approach for HPV propagation was to first expose primary cultured epithelial cells to virus and then to place the cells under the renal capsule of nude mice.²⁵⁵ This immunologically protected site can support the growth of heterologous cells and foster formation of a multilayer epithelium that resembles a stratified squamous epithelium. The xenograft approach led to the successful propagation of several HPV types, although it is too cumbersome for routine virus isolation or for the molecular or biochemical analysis of virus replication.

The complete virus life cycle can be recapitulated in cultured cells by using an organotypic “raft” culture system composed of stratified squamous epithelial cells placed at an air–water interface. This technique is more complex than growing cells in monolayers, and complete replication usually occurs in a small minority of the cells.^{106,410} It can be used, however, to analyze aspects of PV biology, genetics, and biochemistry (Fig. 54.15). Late gene expression can also be studied by suspending HPV-containing epithelial cells in semisolid medium.⁵¹⁶

Efficient methods for generating papillomavirus gene transfer vectors, designated pseudovirions, in monolayer cell culture have been developed.⁷⁴ The most widely employed procedure involves transient expression of codon modified L1 and L2 genes in SV40 T-antigen expressing cells in which high numbers of copies of a target pseudogenome containing the SV40 origin of replication are generated. Pseudovirions containing plasmids expressing marker genes such as GFP or secreted alkaline phosphatase are used in studies of virus infection and *in vitro* neutralization assays.⁴⁶¹ Transfection of authentic recombinant papillomavirus genomes together with an L1 and L2 expressing plasmid that is too large to be packaged in the capsids results in the production of “quasivirus” that can be used as substitute for lesion-derived virions in basic virologic studies.⁴⁸⁴

PAPILLOMAVIRUS INFECTION OF EXPERIMENTAL ANIMALS

The species-specific nature of PV has thus far prevented adaptation of authentic HPV infection to experimental animals. Despite these limitations, several useful animal PV models have been described.⁸⁰

Wild cottontail rabbits (*Sylvilagus floridanus*) represent a natural host for cottontail rabbit papillomavirus.⁵⁵³ Experimental studies of CRPV can be carried out in the natural host, but difficulties in maintaining cottontail rabbits under typical

**A****B**

FIGURE 54.15. Raft cultures showing normal keratinocytes (**A**) and keratinocytes transfected with the full-length HPV16 genome (**B**). The normal keratinocytes stratify and differentiate with an increase in the cytoplasmic-nuclear ratio in cells of the upper half of the epithelium and a prominent granular layer. In keratinocytes transfected with HPV16, while stratification takes place, differentiation is abnormal. There is hyperplasia of cells in the parabasal layer, and mitotic figures are observed in the upper half of the epithelium. No granular layer is seen, and the cytoplasmic-nuclear ratio does not change throughout the stratified epithelium. This morphology is similar to cervical intraepithelial neoplasia (CIN). (Courtesy of D. McCance.)

cage conditions have led to most CRPV studies being carried out with domestic rabbits (*Oryctolagus cuniculus*).⁶⁹ Cottontail and domestic rabbits are closely related species, which probably accounts for the ability of CRPV to infect domestic rabbits. CRPV can readily induce papillomas in domestic rabbits, where their persistence and progression to cutaneous cancer occurs more frequently than in cottontails. Although papillomas in cottontails usually contain large amounts of infectious CRPV, the lesions in domestic rabbits contain little or no infectious virus. Papillomas can also be induced by application of naked CRPV genomic DNA, permitting mutational analyses of the viral life cycle in this model.³²⁹ CRPV genomes have also been incorporated into the L1/L2 capsids of other papil-

lomavirus types and the resulting pseudovirions used to assess the protective capacity of HPV prophylactic vaccines.⁴⁰⁵

Rabbit oral papillomavirus was isolated from domestic rabbits.^{459,662} It is a model for oral mucosal infection without oncogenic potential. Although CRPV and ROPV are closely related phylogenetically, they are sufficiently distinct antigenically that resistance to one virus does not confer resistance to the other.

The canine oral papillomavirus (COPV) causes oral mucosal lesions.⁴³² The papillomas it induces usually regress 1 to 2 months after infection, which makes this model well suited to studying aspects of host defense mechanisms against PV infection.²⁸⁰

BPV1 is the prototype of a group of animal PVs, found in ungulates, that cause fibropapillomas.³⁴⁵ The ability of these PVs to induce nonproductive transformation of dermal fibroblasts leads to their having a wider host range than other PVs, although the increased host range may be limited to fibroblasts. Benign dermal tumors known as *equine sarcoid* appear to arise following accidental dermal infection of horses with BPV1 or BPV2.⁹⁰ An experimental counterpart is the ability to induce nonneuronal tumors in hamsters inoculated intracerebrally with BPV1.

BPV4 can induce oral mucosal lesions in cattle, as well as esophageal papillomas.⁸⁰ When cattle are fed bracken fern that contains chemical carcinogens, it can lead to esophageal cancers. One interesting feature of these cancers is that, although the BPV4 infection plays a role in their induction, the tumors themselves do not contain detectable BPV4 DNA.⁸² This represents a rare instance of virally induced tumors that arise via a “hit-and-run” mechanism.

A rhesus papillomavirus (RhPV) has been described that appears to be sexually transmitted between monkeys and to be associated with the development of cervical cancer.⁶⁷¹ RhPV and HPV16 are highly homologous, which suggests this animal model might have many similarities with human cervical infection with HPV. Infectious RhPV has not yet been isolated or propagated, however, severely limiting experimental analysis of this potentially useful model. The ability to generate RhPV quasivirions in cultured cells might increase the utility of this model.

Cervicovaginal infection by mucosatropic HPVs can be assessed using a pseudovirus-based mouse intravaginal challenge model.⁵⁰⁰ Infection is generally monitored by whole animal luminescence imaging after inoculation with luciferase-expressing pseudovirions. Similar models have been developed to examine cutaneous infection.⁶

The first and only laboratory mouse PV, designated MusPV1, was recently identified and its genomic sequence published.²⁸⁴ The virus was isolated from a colony of immunodeficient inbred mice that spontaneously developed papillomas at cutaneous surfaces near the mucocutaneous junctions of the nose and mouth. Although not yet extensively characterized, this domestic mouse papillomavirus represents a major new tool for applying the power of mouse genetics and immunology to questions of papillomavirus biology.

PAPILLOMAVIRUSES AND CANCER

Whereas some PVs do not appear to have oncogenic potential, a subset of PVs is clearly implicated in the development of

TABLE 54.4 Cancers Associated with Papillomaviruses

Species	Cancer	Predominant virus	Co-factors
Humans	Anogenital tract cancers	HPV16, -18	Tobacco
	Oropharyngeal cancers	HPV16	
	Nonmelanoma skin cancers in patients with EV	HPV5, -8	Sunlight
	Malignant progression of RRP	HPV6, -11	X-Irradiation
Cattle	Alimentary tract cancers	BPV4	Bracken fern
	Eye and skin cancers	Not characterized	Sunlight
Rabbit	Cutaneous cancers	CRPV (Shope virus)	Methylcholanthrene and coal tar (experimentally)

HPV, human papillomavirus; EV, epidermodyplastic verruciformis; RRP, recurrent respiratory papillomatosis; BPV, bovine papillomavirus; CRPV, cottontail rabbit papillomavirus.

malignancy in humans and animals^{69,403,429,699} (Table 54.4). In humans, these include several mucosal epithelial cancers, with cervical cancer being the most important from a public health perspective. HPVs are also implicated in other anogenital cancers, including anal cancer, vulvar cancer, and penile cancer, as well as in oropharyngeal and laryngeal cancers (Fig. 54.16). Although virtually all cases of cervical cancer are attributable to HPV infection, HPV accounts for only a portion of the other cancers. There may be concordant HPV infection at multiple mucosal sites,^{216,607} and patients who have had one HPV-associated cancer may have an increased risk of a second HPV-associated cancer.⁹⁶

In the developing world, cervical cancer accounts for more than 90% of the HPV-associated cancers,¹³² whereas the non-cervical cancers may represent close to one-half of the HPV-associated cancers in the United States and other industrialized countries (Fig. 54.17).⁸⁸ This difference is attributable to substantial reductions in the incidence of cervical cancer brought about by Pap smear screening, as well as an increasing incidence of HPV-positive anal cancer⁴³³ and, especially, HPV-positive oropharyngeal cancer.⁹⁵ In the developing world, less than 5% of HPV-associated cancers occur in males, whereas in the United States approximately 30% of these cancers arise in males.

HPV may also be involved in the cutaneous squamous cell cancers that develop in association with epidermodyplasia verruciformis (EV).⁴⁴⁴ HPVs have also been implicated in some cutaneous squamous cell cancers in the general popula-

tion or in immunosuppressed individuals, but the frequency is unclear.⁴³⁵ Some claims have been made of an association of HPV with several other common cancers, including those of the lung, breast, esophagus, colon and rectum, and prostate, but a consistent causal relationship has not been demonstrated.^{210,325} Except for esophageal cancer, the latter tumor types do not arise in stratified squamous epithelia.

In the well-studied examples of human cancers attributable to HPV, the tumors predominantly develop in a stratified squamous epithelium, they do not occur until many years after the initial infection, persistent infection is required for progression to invasive cancer, and maintenance of the transformed phenotype depends on the continued expression of at least some viral genes, especially E6 and E7. On the other hand, most infections, even those caused by HPV types implicated in cancer, have a benign outcome, either because they are self-limited or do not progress to cancer, even when persistent.

The long interval between the initial infection and the development of cancer implies that, in addition to persistent infection by an appropriate HPV type, additional environmental factors and/or host factors contribute to malignant progression. Immune status is one important host parameter, with impaired cellular immune function being associated with a greater risk of persistent infection and cancer.⁵⁷⁸ Adult patients with Fanconi anemia, an inherited disease with defective DNA repair, have a greater than 100-fold increased risk of developing solid HPV-associated tumors.^{8,340,380} Exogenous exposure

FIGURE 54.16. Worldwide incidence and distribution of cancers attributable to human papillomavirus (HPV). (Adapted from de Martel C, Ferlay J, Franceschi S, et al. Global burden of cancers attributable to infections in 2008: a review and synthetic analysis. *Lancet Oncol* 2012;13:607–615.)

FIGURE 54.17. Annual incidence and distribution of cancers attributable to HPV in the United States (2004–2008). (Adapted from Human papillomavirus-associated cancers—United States, 2004–2008. *MMWR Morb Mortal Wkly Rep* 2012;61:258–261.)

of PV-induced lesions to cocarcinogens may represent an environmental mechanism. For example, most cutaneous cancers in EV occur on sun-exposed skin, which implies that UV light is serving as a co-carcinogen.

Most HPV-associated cancers appear to depend on the continuous expression of viral genes (e.g., E6 and E7). However, it remains possible that viral gene expression may not be obligatory at all stages for some HPV-induced cancers. In a small minority of human tumors that contain HPV DNA, viral gene expression seems to have been selectively suppressed.²²² Development of esophageal cancer in cattle by BPV4 and the carcinogen in bracken fern is associated with complete loss of the viral genome in the malignant tumor.⁴²⁹ This hit-and-run phenomenon suggests that in these instances the virus is required for tumor induction, but that its continued presence is selected against in progressed lesions.

HUMAN PAPILLOMAVIRUS INFECTIONS OF THE GENITAL TRACT

HPV infection of the anogenital tract represents the most important medical burden from infection with this group of agents (Table 54.5). Infection affects the genital skin and mucosa, including the vaginal tract, cervix, and anal canal. Most of these infections are sexually transmitted, which means that their prevalence is usually correlated with measures of sexual promiscuity, such as number of lifetime sexual partners, a recent change in sexual partner(s), and a history of other sexually transmitted infections.

HPV infection of the anogenital tract is extremely common, with a wide range of clinical manifestations and outcomes, varying from asymptomatic and self-limited, to persistent and associated with malignant progression. Viral factors and host factors each contribute to determining the outcome. The alpha-HPVs cause most anogenital infections, and the majority of oncogenic HPV types are from the alpha-7 and alpha-9 species (see Fig. 54.1).

Cervical Cancer

Cervical cancer is the third most common malignancy among women worldwide, with approximately 530,000 newly diagnosed cases each year and about 275,000 deaths annually.^{17,132}

Despite its worldwide distribution, the frequency of cervical cancer varies considerably, being about 10 times more common in some developing countries than in some industrialized ones. More than 85% of cervical cancer occurs in developing countries, where it is frequently the most common cancer of women, accounting for as many as one-fourth of female cancers. Pap smear screening has decreased the frequency of cervical cancer in industrialized countries. In the United States, approximately 12,000 new cases are diagnosed annually,⁸⁸ and about one-third of these women will die of their malignant disease. The

TABLE 54.5 Major Clinical Association of Genital Tract and Other Mucosal Human Papillomavirus (HPV)	
Clinical association	Viral type(s)
Genital tract	
Subclinical infection	All genital HPV
Exophytic condyloma (any site)	HPV6, -11
Flat condyloma (especially cervix)	HPV6, -11, -16, -18, -31, others

FIGURE 54.18. Progression from a benign cervical condylomatous lesion to invasive carcinoma. Infection by oncogenic human papillomavirus (HPV) types, especially HPV-16, may directly cause a benign condylomatous lesion, low-grade dysplasia, or sometimes even an early high-grade lesion. Carcinoma *in situ* rarely occurs until several years after infection. It results from the combined effects of HPV genes, particularly those encoding E6 and E7, usually after integration of the viral DNA into the host DNA and a series of genetic and epigenetic changes in cellular genes. HSIL, high-grade squamous intraepithelial lesion; LSIL, low-grade squamous intraepithelial lesion; CIN, cervical intraepithelial neoplasia. (Modified from Lowy DR, Schiller JT. Prophylactic human papillomavirus vaccines. *J Clin Invest* 2006;116:1167–1173.)

incidence of cervical cancer in the United States varies considerably between ethnic and, especially, socioeconomic groups.¹⁹¹

Most cancers occur in the transformation zone of the cervix, where the columnar cells of the endocervix form a junction with the stratified squamous epithelium of the exocervix.^{439,527} About 85% of cervical cancers are squamous cell cancers. Most of the other cases are adenocarcinomas, with a small number being small cell neuroendocrine tumors.

Lesions that are destined to become malignant squamous cell carcinomas typically undergo a series of dysplastic changes over many years. The severity of the lesion is determined by the degree to which the squamous epithelium is replaced by basaloid cells, with the entire thickness being replaced in the most severe dysplasias. In the histologic classification of cervical intraepithelial neoplasia (CIN), grades 1, 2, and 3 correspond, respectively, to mild dysplasia, moderate dysplasia, and severe dysplasia or carcinoma *in situ* (Fig. 54.18). The cervical dysplasias have their counterpart in the exfoliated cells present in the Papanicolaou (Pap) smear, by the presence of basaloid cells and koilocytosis. In the cytologic Bethesda System,³³⁹ abnormalities are classified as low-grade and high-grade squamous

intraepithelial lesions (SIL) with low-grade corresponding to mild cytologic abnormalities, and high-grade encompassing the more severe abnormalities (Fig. 54.19). Atypical squamous cytology of undetermined significance (ASCUS) is the cytologic designation for equivocal lesions.

Most dysplasias do not progress and, in fact, resolve spontaneously, with the likelihood of resolution decreasing with the severity of the dysplasia (Fig. 54.20). More severe dysplasias, however, generally arise from less dysplastic lesions after several years,^{289,364} although some high-grade dysplasias can develop rapidly without passing through a low-grade stage.³²⁶ Because of the long interval between the development of cervical dysplasia and invasive cancer, Pap smear screening programs can identify most premalignant lesions. Appropriate follow-up of women with these abnormalities, together with appropriate treatment, can thereby prevent the development of most cases of cervical cancer. In some countries with screening programs, however, the incidence of adenocarcinoma and adenosquamous cell carcinoma has been increasing, suggesting that Pap smear screening is less effective in identifying the precursors to these tumor types.^{77,551,638}

FIGURE 54.19. Changes in the human papillomavirus (HPV)-16 life cycle from cervical intraepithelial neoplasia (CIN)1 to CIN3. During progression, normal regulation of the papillomavirus life cycle is lost. CIN1 lesions generally resemble productive lesions caused by other supergroup A HPV types, and express virus coat proteins at the epithelial surface. In CIN2 and CIN3, the order of life cycle events is unchanged, but the extent of E7 expression is increased. (Reproduced from Doorbar J. The papillomavirus life cycle. *J Clin Virol* 2005;32(Suppl 1):S7–15, with permission.)

FIGURE 54.20. Natural history of cervical human papillomavirus (HPV) infection. Approximate number of U.S. cases of the different categories of infection. Most subclinical infections and low-grade dysplasias regress spontaneously. Even high-grade dysplasia has some potential to regress spontaneously. Infection with HPV-16 or HPV-18 represent a minority of subclinical infections and low-grade dysplasias, while they represent a majority of the high-grade dysplasias and invasive cancers.

Role of HPV in Cervical Cancer

Cervical cancer was recognized for decades to behave as a sexually transmitted disease, long before sexually transmitted HPV infection was implicated in its pathogenesis. In the mid-1970s, Meisels and Fortin⁴⁰⁴ recognized, on morphologic grounds, that HPV infection of the cervix occurred frequently, often with the histologic characteristics of mild CIN. These observations coincided with the proposal by zur Hausen⁶⁹⁸ that HPV infection might be the putative sexually transmitted agent responsible for cervical cancer. The CRPV system had provided the initial experimental evidence that animal PV could induce malignant tumors, whereas ROPV lacked oncogenic activity. The development of skin cancer in patients with EV had demonstrated that some HPV might have malignant potential.^{383,444} As with ROPV, only a subset of the HPV types isolated from patients with EV was found in the skin cancers, implying that HPV types might vary in their oncogenicity. The identification in the early 1980s of HPV16 and HPV18 by zur Hausen and colleagues^{56,162} provided the field with HPV types that could be shown to be present in most cervical cancers and could, by lower stringency hybridization techniques, identify HPV DNA in an even greater proportion of these tumors. Subsequent studies, carried out by many investigators, have sought to understand the natural history of HPV infection of the genital tract, determine the biologic properties of different HPV types, elucidate the role of the virus in the pathogenesis of cervical disease, and identify nonviral factors that may influence the outcome of HPV infection.

About 40 HPV types, mostly from the alpha genus, can infect the genital tract. Only a subset of these types, however, is found regularly in cervical cancers, and in a higher proportion than in controls, leading these types to be designated as *high-risk*. On the other hand, HPV types that are found less frequently in tumors than in controls are designated *low-risk*. A worldwide study of almost 1,000 cervical cancers, from paraffin-embedded sections, indicated that more than 90% contain HPV DNA.⁵⁵ The results confirmed and extended observations made in more restricted studies of cervical cancer.²⁷¹ Although more than 20 HPV types were found in the tumors, four types (HPV16, HPV18, HPV31, and HPV45), from the alpha-7 (types 18 and 45), and alpha-9 (types 16 and 31) species, accounted for close to 80% of the HPV-positive cancers. Conversely, low-risk HPV

(e.g., HPV6 and HPV11) was found in only two of these cancers. In almost all areas of the world, HPV16 is the most common type found in the cancers. Some regional variation exists in the specific proportion of HPV types.⁵⁶⁴ A follow-up evaluation of the cancers in the international study that were initially believed to be HPV-negative indicated either that they were false-negative results, or that the DNA in the specimens was too degraded for the negative results to be deemed reliable.⁶⁴² The conclusion from this study was that at least 99.9% of cervical cancers contain HPV DNA. Subsequent systematic assessment of a group of CIN3 and invasive cancers also supports the conclusion that virtually all bona fide cases are associated with HPV DNA.⁴⁹ Likely, cases reported as being HPV DNA-negative represent false-negative findings.

An international analysis of 1,918 cases of squamous cell cancers and 1,928 controls pooled from 11 case-control studies identified 15 HPV types as high-risk, three additional ones as probably high-risk, and 11 types as low-risk (Table 54.6).⁴²³ Of the cases, 90.7% were HPV DNA-positive. Eight of the HPV types (16, 18, 31, 33, 45, 52, 58, and 35) accounted for 95% of the positive cases. With two exceptions (HPV70 and HPV73), the phylogenetic relationship between the HPV types correlated perfectly with the high-risk or low-risk potential of the types. The odds ratios for developing cervical cancer associated with HPV16 and HPV18 were 434 (95% confidence interval [CI] 278–678) and 248 (95% CI 138–445), respectively. Although other high-risk types also had high odds ratios, HPV16 and HPV18 were the only HPV types whose lower limit 95% CI was greater than 100. These odds ratios are among the highest for a human carcinogen. In a worldwide meta-analysis of 14,595 cervical cancers, of which 89.7% were HPV-positive, HPV16 accounted for 55.2%, followed by -18 (12.8%), -45 (4.6%), -31 (3.8%), and -33 (3.7%).⁵⁶⁴ Prospective population-based studies in the United States and Europe that used progression from asymptomatic infection to CIN3 or worse (CIN3+) as the end point confirmed that HPV16 is the most oncogenic type, with the next most virulent types appearing to be HPV18, -31, and -33 (Fig. 54.21).^{316,528}

Whereas most studies have focused on the more common squamous cell cancers, most adenocarcinomas, adenosquamous carcinomas, and those carcinomas with neuroendocrine differentiation also contain HPV DNA.^{7,87} In an international

TABLE 54.6 Phylogenetic and Epidemiologic Classification of Human Papillomavirus (HPV) Types, Based on Presence or Absence in Cervical Cancer

Phylogenetic classification	Epidemiologic classification		
	High-risk	Probable High-risk	Low-risk
High-risk	16, 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, 68, 82	26, 53, 66	70
Low-risk	73		6, 11, 40, 42, 43, 44, 54, 61, 70, 72, 81, cand-89

analysis that pooled eight case-control studies, 81% of the tumors were HPV DNA-positive, and HPV16 and HPV18 accounted for 81% of these tumors.⁸⁷ More of these tumors are associated with HPV18, compared with squamous cell carcinomas, and in some studies the number of HPV18-associated tumors is greater than those associated with HPV16. Some evidence suggests that HPV18 infection may progress more rapidly and carry a poorer prognosis than HPV16.

The distinction between high-risk and low-risk HPV types has considerable utility, but should not be overinterpreted. Even low-risk HPV types may rarely be associated with cervical cancer.²²² HPV6 and HPV11 isolated from cervical cancers may have alterations in their genome that could have increased their oncogenic potential. Alternatively, an HPV type, such as HPV26, might be more oncogenic in an immunocompromised host.²³⁸ It should also be recognized that this classification may not apply to HPV infections in all sites. For example, the Buschke-Lowenstein tumor, which is a low-grade squamous cell carcinoma of the external genitalia, is usually associated with the low-risk HPV6 or HPV11.²²⁸ Laryngeal cancer complicating recurrent respiratory papillomatosis (RRP) may also involve these low-risk types,³⁶⁶ although most HPV-positive laryngeal cancers arise in patients without RRP and contain a high-risk HPV, especially HPV16.¹⁵⁹

Natural History of Genital Human Papillomavirus Infection

Genital HPV infection is considered the most common sexually transmitted viral infection, with an estimated life-time risk of at least 75%.^{26,239,530} The estimated prevalence of infection varies with the age of the population and depends on the sensitivity of the HPV assay employed. A recent population-based study of cervical infection in the United States, which used a very sensitive DNA-based test, found 42.5% of women age 14 to 59 were HPV-positive, with those age 20 to 24 having the highest prevalence, 53.8%, decreasing to 38.8% in women age 50 to 59 (Fig. 54.22). The infections were divided approximately equally between high-risk and low-risk types. Because sexually active women 19 or younger acquire genital HPV infection at a high rate,^{252,672} the comparatively low prevalence of 32.9% among those 14 to 19 probably arises because many in this age group are not yet sexually active. The decreasing prevalence of HPV infection beyond age 24 results from a combination of the self-limited nature of most infections, decreasing HPV exposure with age, and resistance to reinfection. It is known that HPV can establish latency,^{151,178,391} but it is not clear whether to attribute increased detection at this age to a decrease in immune surveillance, a cohort effect, or some other explanation.

FIGURE 54.21. Data from the Danish Cohort Study shows that the human papillomavirus (HPV) type affects the rate of development of cervical intraepithelial neoplasia (CIN)3 or worse in women with normal cytologic findings at baseline.³¹⁶

FIGURE 54.22. Distribution of prevalent cervical infection by high-risk and low-risk human papillomavirus (HPV) types in U.S. women 14 to 59 years old. (Adapted from Hariri S, Unger ER, Sternberg M, et al. Prevalence of genital human papillomavirus among females in the United States, the National Health and Nutrition Examination Survey, 2003–2006. *J Infect Dis* 2011;204:566–573.)

The natural history of genital HPV infection in men has been studied less systematically than in women.^{213,460} As with women, male infections are very common, and most are self-limited. In males, however, prevalence does not tend to decrease with age.²¹⁴ When controlled for lifetime number of sexual partners, male circumcision has been identified as an important negative risk factor for the prevalent infection in the men and for cervical cancer in their current sexual partners.^{4,86}

Although most women with HPV infection of the genital tract do not have detectable cytologic abnormalities, the epidemiology of genital HPV infection appears to account for the epidemiology of cervical neoplasia, including the dysplasias that precede cervical carcinoma.⁵⁴ Following the development of validated HPV DNA assays,^{497,566} many studies have consistently shown that infection with high-risk HPV represents the major risk factor for high-grade cervical dysplasias and invasive cancer.^{88,54,316,528} In cytologically normal women, being positive for a high-risk HPV places them at much higher risk

for developing cytologic abnormalities compared with women who are HPV-negative.^{316,326,528} In addition, results of a validated serologic assay that can identify currently and previously infected individuals implicated HPV16-related viruses prospectively in the development of cervical cancer.³⁵⁸

As noted above, most genital infections are self-limited, and the majority clear within 12 months.^{26,252,667,672} Clearance of HPV infection appears to return an individual to the same low risk of CIN3 or invasive cancer as an individual in whom HPV has not been detected previously. Low-grade dysplasia may be caused by infection with either low-risk or high-risk HPV. Persistent (i.e., long-term) infection with a high-risk HPV type, which occurs in a minority of infected women, is the single most important risk factor for developing CIN3 or invasive cancer (CIN3+). However, the magnitude of the risk depends on the HPV type (Fig. 54.21), and even on the variant within a given type.⁵³¹ In practical terms, persistence is usually defined as meaning that the same HPV type has been identified in two or more genital samples taken over a certain period, with the interval usually being 4 to 12 months. Persistent infections may clear spontaneously, but are less likely to do so the longer they persist. Conversely, only some persistent infections progress to CIN3, and only some CIN3 progress to invasive cancer (Fig. 54.23). HPV16 infections are more likely to persist than infection by other HPV types.³⁶⁵ However, persistence *per se* is not sufficient for progression to high-grade dysplasia, because low-risk HPV types that persist are much less likely to progress than high-risk types.⁵²⁹ The distinct biologic activities of high-risk E6 and E7 are likely to represent at least partial explanations of the differences in the likelihood of progression. Despite some enthusiasm for quantitative measurement of viral loads, their presence has not been consistently associated with progression to high-grade disease.^{377,678}

As persistent infection with a high-risk HPV constitutes the main risk factor for progression to CIN3 or invasive cancer and high-risk HPV DNA is found in virtually all cases of cervical cancer,⁶⁴² it has been concluded that HPV infection is

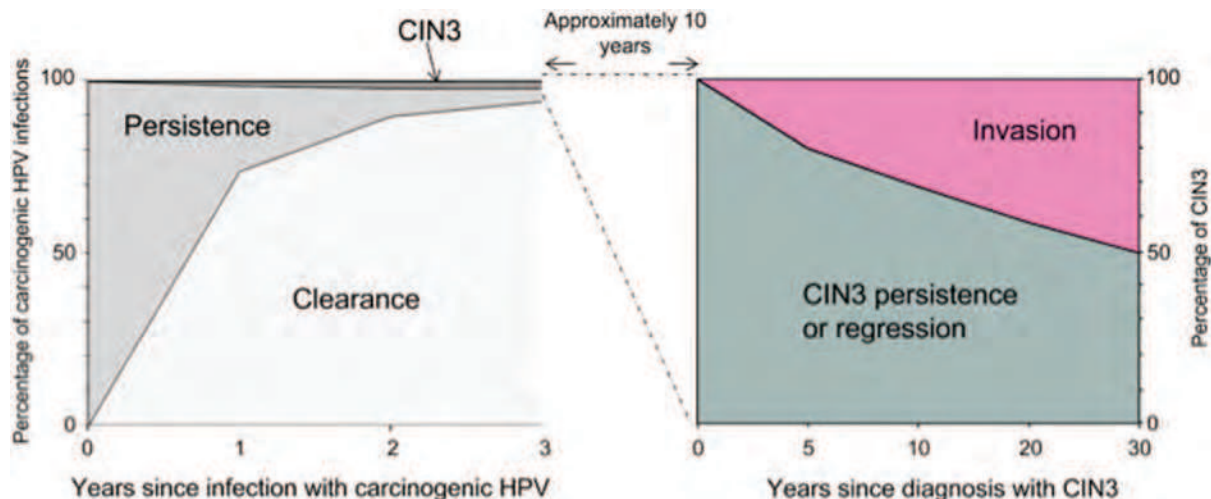

FIGURE 54.23. Risk of persistent human papillomavirus (HPV) infection and progression to cervical intraepithelial neoplasia (CIN)3 and invasive cervical cancer. (Reprinted from Schiffman M, Wentzensen N, Wacholder S, et al. Human papillomavirus testing in the prevention of cervical cancer. *J Natl Cancer Inst* 2011;103:368–383, with permission.)

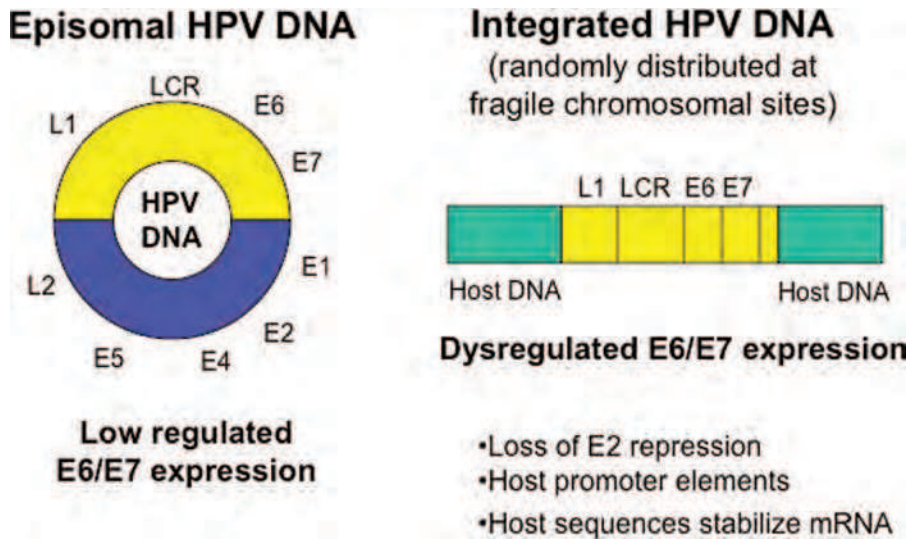

FIGURE 54.24. Integration of human papillomavirus (HPV) DNA results in high-level expression of E6 and E7. In low-grade lesions, the viral genome is maintained as an episome, which is associated with low level expression of E6 and E7. Viral DNA integration into the host DNA, which occurs in high-grade dysplasia or cancer, is usually associated with deletion of portions of the viral genome, with preferential retention of the long control region (LCR) E6-E7 region and the higher levels of expression of E6 and E7, attributable to multiple factors.

a necessary cause of cervical cancer. Persistent HPV infection, however, is not sufficient to cause cancer, because some individuals who have persistent infection with a high-risk HPV do not develop serious lesions.

Molecular Pathogenesis of Cervical Cancer

High-risk HPV types can infect the genital skin, the vaginal tract, or the cervix. If the cervix is not infected initially, the virus must spread locally, by autoinoculation, to the cervix for the individual to be at risk of developing cervical lesions. These can be single or multiple, and only develop in cells that have been infected. A recently identified subset of cervical cells in the transformation zone that expresses specific markers may be particularly susceptible to tumor development when they become infected.²⁴⁷ The production of progeny virions is usually limited to asymptomatic or low-grade lesions, as the full viral replication cycle is tied to the differentiation process.¹⁵¹

In high-grade dysplasias, a more restricted number of viral genes are expressed, primarily E6 and E7, and their expression is now found in the basal, proliferating layer of the epithelium, in contrast to most of their expression being in suprabasal cells during productive infection. E6 protein is expressed at substantially lower levels than E7, and in early lesions, the level of E7 may be more limiting than E6.⁵¹² Both genes are expressed from a single promoter, with alternate splicing determining their relative level of expression,⁶⁰⁶ and progression to high-grade disease may be associated with a splicing pattern that favors E7 production. E6 and E7, which have many activities, appear to be the main drivers for progression to high-grade dysplasia and cancer, by orchestrating a series of pathogenetic changes. Methylation of the HPV16 viral genome appears to change the risk of progression to moderate or high-grade disease, with methylation of CpG sites in L1, L2, and E2/E4 being associated with an increased risk of precancer,⁴¹⁴ whereas methylation of LCR sites is associated with a decreased risk.⁵⁹⁰

Integration of HPV DNA, via nonhomologous recombination, represents a key change that appears to stabilize the high expression of E6/E7 and is frequently associated with more severe lesions. In one study of 155 samples, integration was not detected in any normal or CIN1 lesions, but was present in 5%

of CIN2 lesions, in 16% of CIN3 lesions, and in 87% of invasive cancer.³¹⁹ Other studies suggest that integration occurs in a higher proportion of CIN3 lesions.²⁵⁴ The frequency of viral DNA integration may vary with the HPV type, being integrated in most tumors with HPV18 and -45, more than one-half of those with HPV16, and less than 40% of those with HPV31 and -33, using an assay that determines whether the viral RNA originates from integrated or unintegrated DNA.⁶³⁵ Viral DNA integration can occur at many sites throughout the genome, but is found preferentially at genomic fragile sites.^{615,653} In a given lesion, it usually involves only one locus or a few loci.⁶⁹⁵

Viral DNA integration is characteristically associated with deletion of large segments of the viral genome, and with transcription of sequences downstream from the integrated LCR (Fig. 54.24).⁵³⁷ In this integrated form, the E6 and E7 ORFs remain intact in the integrated viral DNA, and can be transcribed from the LCR, which lies upstream in the integration site. Experimental data suggest that disruption of the viral E1 and E2 genes, as well as of downstream viral sequences, may permit higher levels of E6 and E7 transcription,^{282,505} whose RNA may be stabilized following fusion to downstream cellular sequences, but integration is not invariably associated with higher levels of expression.²³² Cellular promoter elements near the integration site may also contribute to increased viral gene expression. When more than one viral DNA integration site exists, viral gene expression from a single site predominates via methylation of the other sites.^{292,630}

Viral DNA integration occurs in almost all tumors and tumor-derived cell lines that harbor HPV18, and in most with HPV16, although the DNA remains episomal in some HPV16 tumors and cell lines.^{122,635} Cell lines derived from cervical cancer continue to express E6 and E7, which appear to be necessary for their continued viability and their ability to proliferate.^{136,140} It is noteworthy that HPV16- and HPV18-positive cell lines derived from cervical and anal cancers harbor wild-type versions of p53 and pRb, in contrast to HPV-negative tumor-derived cell lines, many of which have mutant p53 and pRb.^{119,120,523,674} This observation implies that there is sufficient functional inactivation of p53 and pRb by HPV E6 and E7 and that there is virtually no selective pressure for the

genetic inactivation of the *p53* and *pRb* genes. Another consistent feature of dysplasias and cancer is that most cells express p16, as a cellular response to the E7-dependent inactivation of pRb,^{520,639,651} again in contrast to many tumors not associated with HPV, in which p16 tends to be silenced.

High-risk HPV induce abnormal centrosome duplication, which can result in genomic instability and aneuploidy.^{157,474} The deregulation of this mitotic event appears to depend on both E6 and E7, with the latter protein being more responsible for the effect.³²⁴ Aneuploidy may result in part from an association between E7 and NuMA (nuclear mitotic apparatus protein 1).⁴³¹ In a study that compared the incidence of aneuploidy and viral DNA integration, both were associated with increasing dysplasia.⁴⁰⁷ Although 95% (19 of 20) of lesions with integrated viral DNA were aneuploid, only 59% (19 of 32) of aneuploid lesions had integrated viral genomes. Because aneuploidy was found significantly more frequently than integration, it was concluded that deregulated viral oncogene expression results first in chromosomal instability and aneuploidization, which are subsequently followed by viral DNA integration.

The activation of telomerase (hTERT) represents another important HPV-dependent effect relevant to cancer.^{315,320} In human keratinocytes, this activity is induced primarily by E6 through a mechanism that is largely independent of p53 and probably includes an interaction with hTERT complexes.³⁷⁰ Efficient immortalization of keratinocytes by E6 and E7 probably depends on the ability of E6 to inactivate p53 and to activate telomerase, although E7 also contributes to this process, and keratinocyte immortalization can be induced by E7 plus either a mutant p53 or the catalytic component of telomerase. In the context of the viral genome, factors in addition to E6 may also contribute to hTERT activation.^{576,580} In cervical lesions, hTERT activation is associated with progression to severe dysplasia and cervical cancer, and cell lines derived from cervical cancers are uniformly positive for hTERT.^{303,567} A gene may exist on chromosome 6 that antagonizes HPV-induced activation of telomerase, as suggested by *in vitro* studies⁵⁸⁰ and by finding increased allelic imbalances at 6q14-q22 in CIN3 and cervical cancer with elevated telomerase activity.⁶²⁷

Although the studies mentioned above imply a central role for high-risk E6 and E7 genes in cervical cancer pathogenesis since tumors that contain only integrated HPV DNA have usually lost the E5 gene, evidence suggests that, in HPV16-associated tumors that retain extrachromosomal copies of the viral genome, E5 may also contribute to their pathogenesis. In one study, HPV16 E5 protein was detected in 12 (60%) of 20 of invasive cancers.⁹² Of the 12 E5-positive cases, 3 cases contained only episomal forms, whereas the other 9 had both episomal and integrated HPV DNA. The presence of E5 protein was significantly associated with the high-level expression of EGF-R and of the related ErbB4 protein. Consistent with the inference that E5 expression in the tumors has pathogenetic relevance, E5 in mice can stimulate hyperplasia that depends on EGFR,²⁰² and induce cervical tumors whose efficiency is increased by E6 or E7.³⁹⁷

Cellular Events in Cervical Cancer

Although infection with high-risk HPV may be necessary for the development of cervical cancer, or other cancers attributable to HPV infection, it is clearly not sufficient. Cancer must arise only after other factors have collaborated with the infection. As

discussed above, some changes (e.g., integration) may be virus-specific. Other changes associated with progression include genetic and epigenetic alteration of cellular genes. These alterations, which reflect the consequence of long-term viral gene expression, especially E6/E7, include downregulation of tumor suppressor genes and proapoptotic genes, or upregulation of protooncogenes and antiapoptotic genes.^{301,352,420,565} The specific changes are heterogeneous, although some occur relatively frequently. Epigenetic silencing of numerous genes has been reported in high-grade dysplasias and cancer.^{150,177,600,652} Tumors typically have several cytogenetic alterations, which implies loss or gain of function of several cellular genes. In most instances, the specific gene that has been affected by a given cytogenetic alteration has not been unequivocally identified. Whereas most of these cytogenetic changes are probably not a direct consequence of viral DNA integration, cellular genes can be directly affected by the viral integration. For example, viral DNA integration near the c-Myc protooncogene occurs in about 10% of cervical cancer and has been associated with its increased expression.^{160,653}

Consistent with the multistep nature of tumorigenesis, cervical cancers may show additional cytogenetic alterations when compared with adjacent dysplastic lesions.³⁰⁷ Some cytogenetic changes have been found in a relatively high proportion of tumors.³⁵² Those found in one-fourth to one-half of tumors include loss of heterozygosity in chromosome regions 3p14, 4p16, 4q21-35, 6p21-22, 11p15, 11q23, 17p13.3, and 18q12-22. Loss of heterozygosity in 3p has been identified in cervical dysplasias adjacent to cancers that also have this alteration.²³¹ This observation implies that inactivation of a putative tumor suppressor gene in this region may occur as an early event that could predispose to further progression. The *FHIT* (fragile histidine triad) gene, which is a putative tumor suppressor gene, is a candidate for the 3p locus. It is located at 3p14.2, and its expression is inversely correlated with the severity of dysplasia or cancer and with prognosis.^{44,258} The tumor suppressor of lung cancer 1 (TSLC1) gene, which is implicated in mediated cell adhesion, may be the tumor suppressor gene associated with loss of 11q23.^{579,683}

In contrast to the multiple loci with loss of heterozygosity, a gain of chromosome 3q24-28 has been reported to be present in almost all cervical cancers, but to be absent from most cases of severe dysplasia.²⁴⁹ The gene encoding the catalytic subunit of the class 1A phosphatidylinositol 3-kinase (PIK3CA), which is located in 3q26.3 and is part of the PI3 kinase/AKT signaling pathway, has been proposed as a candidate oncogene for this amplified locus.³⁸⁵ The PI3 kinase/AKT pathway, which promotes growth and is antiapoptotic, is active in most cervical tumors. This activity is associated with inactivation of the phosphatase and tensin homolog (PTEN) tumor suppressor gene and frequent PIK3CA amplification.^{41,102} EGF-R overexpression may also have prognostic significance.^{306,438}

Evidence suggests that cervical cancers have undergone changes that may help them to evade the immune system,^{190,294,582} whereas the presence of T regulatory cells in the tumor microenvironment may interfere with the ability of the immune system to mount a strong response against the tumor.^{472,625} The most frequent changes in the tumor cell involves the downregulation of HLA antigen class I alleles, which are normally expressed on keratinocytes, in contrast to class II.^{118,583} Consistent with a role in progression, downregulation

of one or more class I alleles occurs in most tumors, and is reported to be greater in metastases compared with the primary tumor. Patients who are HLA-B7 positive whose tumors downregulate this allele have a poorer prognosis, and selective loss of HLA-B7/40 allelic products is associated with lymph node metastases. Several mechanisms may account for the downregulation of class I expression.^{63,118,323} Some affect class I alleles directly by mutation or deletion, whereas others affect the class I processing system, primarily by downregulation of the TapI transporter, which is required for class I processing. The HLA antigen region is located on the short arm of chromosome 6, at 6p21.3, which is within the 6p21-22 region that, as noted above, has been reported to be a frequent site of cytogenetic abnormalities in cervical cancer. Therefore, it is likely that many of the cytogenetic rearrangements in this region reflect alterations in class I alleles. In addition to these class I changes, most primary tumors aberrantly express HLA antigen class II molecules, perhaps in response to inflammatory cytokines produced by infiltrating lymphocytes. Class II expression is not a feature of metastatic lesions.

Other Co-factors in Cervical Cancer

Because only a few women infected with high-risk HPV are destined to have a malignant outcome, host and environmental factors have been examined for their possible influence on the incidence of cervical cancer and its precursor lesions.^{85,93} When controlled for the presence of HPV infection, smoking, oral contraceptives, early age of pregnancy, and multiparity have consistently been found to be associated with increased risk,^{16,15,86} with nutrition, micronutrients, and other sexually transmitted diseases⁵⁶³ to be associated with increased risk in some studies. In most instances, it is not clear how the co-factor contributes to dysplasia and carcinogenesis. Possibilities include increasing the risk of establishing infection, decreasing local or

systemic immunity, stimulating the growth of HPV-infected tissue, and inducing mutations in infected tissue. It may be relevant that higher levels of a tobacco-specific carcinogen have been identified in the cervical mucus of cigarette smokers.⁴⁸³ Although not all studies have found positive results, specific alleles of some immune response genes appear to be associated with susceptibility to, or protection from, serious HPV infection. These include HLA antigen class I and II genes and killer immunoglobulin-like receptor (KIR) genes, which recognize specific HLA antigen class I allotypes.^{83,93}

Human Papillomavirus in Other Genital Sites Anogenital Warts (Condylomas)

As with cervical HPV infection, condylomas are most prevalent among young, sexually active adults, and their frequency usually parallels that of other sexually transmitted conditions (Fig. 54.25).^{26,318,460} The estimated prevalence in the United States is 1% of the sexually active population aged 15 to 49, with about 7% of women and 4% of men giving history of at least one episode.¹⁴⁶ The increase in sexual promiscuity that began in the mid-1960s was associated with at least a four-fold increase in the incidence of condylomas, which decreased by about one-third in the 1990s, and increased about twofold between 2000 and 2010. Infection may be subclinical.⁶⁰

Condylomas are usually exophytic lesions that are frequently multiple. They can arise anywhere on the external genitalia and can be found simultaneously in multiple sites. In men, they occur most commonly on the penis and anus, and in women on the perineum and anus. The anus can develop multiple lesions that coalesce to surround the anal canal. Condylomas are usually self-limited, regressing spontaneously or after local treatment, but some lesions can persist for years. As with other HPV infections, genital warts, when they arise in patients with impaired cellular immunity, can be extremely

FIGURE 54.25. Proportion of self-reported clinically diagnosed genital warts during the last 12 months by age and country. (Adapted from Kjaer SK, Tran TN, Sørensen P, et al. The burden of genital warts: a study of nearly 70,000 women from the general female population in the 4 Nordic countries. *J Infect Dis* 2007;196:1447–1454.)

refractory to treatment. They can also increase in size and number during pregnancy, and regress following delivery. This sequence of events may also be a reflection of the immune suppression associated with pregnancy.

About 90% of genital warts are caused by HPV6 or HPV11, which are closely related to each other, with HPV6 predominating.²²³ Other HPV types, including HPV16, may also be found in these lesions. Bowenoid papulosis is a related entity.²²⁴ The lesions usually consist of multiple small papules that histologically resemble Bowen's disease or squamous cell carcinoma *in situ*. Most of these lesions contain HPV16, but the rate of transition to frank malignancy appears to be much lower for the external genitalia than for the cervix. Some genital warts in children may be sexually transmitted, secondary to sexual abuse.^{111,441} Genital lesions in children, however, can commonly result from virus inoculation at birth or from incidental spread from cutaneous warts. In contrast to anogenital lesions in adults, a significant proportion of genital warts in children contain HPV types that are usually isolated from nongenital warts, perhaps because, compared with adults, the genital skin in children is more susceptible to infection with these nongenital HPV types.

Vulvar, Vaginal, and Penile Malignancy

Genital HPV can routinely infect other genital areas that contain stratified squamous epithelium. The risks associated with HPV infection at these sites appear to be similar to that of cervical infection. HPV DNA, usually HPV16, is found in a subset of cancers of the vulva, vagina, and penis.^{20,562} Giant condyloma acuminata, also called the Buschke-Lowenstein tumor, is a low-grade, locally invasive squamous cell carcinoma that involves the external genitalia, most frequently the penis. It is associated with low-grade HPV types, such as HPV6 and HPV11.^{228,394}

In squamous cell carcinoma of the vulva, most invasive tumors designated morphologically as being warty or basaloid arise in younger women and contain HPV DNA, especially HPV16.²¹⁰ Smoking and infection with herpes simplex virus type 2 have been identified as possible co-factors for vulvar cancer. Vulvar and vaginal dysplasia occur more frequently in women with a previous history of cervical dysplasia,¹⁴⁸ and some evidence, based on virus-host DNA junction analysis, suggests that, in some instances, dysplastic cells may actually have been self-transplanted from the cervix to these sites.⁶³⁴ In contrast to basaloid vulvar cancers, HPV DNA is found in only a few keratinizing squamous cell carcinomas of the vulva, which is associated with older women and with mutation of p53.

Anal Cancer

Anal cancer shares important similarities with cervical cancer, as well as some differences. The disease is somewhat more frequent in women than in men, with about 3,100 female cases and 1,700 male cases per year in the United States.⁸⁸ The incidence has been gradually increasing since the mid-1980s, with a similar rate of increase in men and women between 1992 and 2004.²⁹⁰ Anal HPV infection appears to be sexually transmitted in most instances, and a history of receptive anal intercourse in women and of homosexual activity in men is associated with an increased risk for this cancer.¹⁹³ Such a history is often lacking, however, which makes it likely that some anal infections have spread from other genital areas. Consistent with this interpretation, simultaneous cervical and anal infection, often with the same HPV type, is common. The rate of anal infection by HPV appears to be

similar to that of cervical infection, although anal HPV infection has been studied less systematically than cervical infection.⁶⁶³ As with cervical cancer, high-risk HPV has been found in most anal cancers, with an even greater preponderance of HPV16 than in cervical cancer, and most anal cancers arise in the transition zone between columnar and squamous epithelium. In one large study from Scandinavia, 83% of HPV-positive tumors contained HPV16, and 93% of tumors from women were HPV positive, whereas 69% of the tumors from men were HPV positive.¹⁹³ A meta-analysis of anal cancer drew qualitatively similar conclusions: 86.5% of female cases were HPV positive, compared with 76.7% of male cases.²⁵³ It would appear, therefore, that most anal cancers in women are attributable to HPV infection, whereas some proportion of anal cancers in men may not be.

One important difference from cervical cancer is that the risk of anal cancer in the general population appears to be much lower than for cervical cancer, although it is not known what may account for these differences in rates of progression. In countries with effective cervical cancer screening programs, comparisons between the incidence of cervical cancer and anal cancer underestimate the difference in risk of progression because these programs prevent many potential cases of cervical cancer. In developing countries, however, where almost no impact exists of Pap smear screening on the incidence of cervical cancer, the incidence of anal cancer in women is less than one-tenth that of cervical cancer.

The risk of anal cancer among individuals who are human immunodeficiency virus (HIV) positive is much greater than in the general population, with especially high rates for HIV-positive male homosexuals.⁴⁵⁵ According to the AIDS-Cancer Match Registry Study in the United States, HIV infection was associated with a relative risk, for invasive cancer, of 6.8 for women and 37.9 for men.¹⁹² The difference in risk between women and men was attributable to the group of HIV-positive homosexual men, whose relative risk was 59.5, compared with a relative risk of 5.9 for male HIV-positive male intravenous drug users. As discussed in more detail below, a high proportion of men and women with HIV infection also have anal HPV infection and associated dysplasia.¹³³ Studies from San Francisco report anal HPV infection in 93% of HIV-positive male homosexuals (versus 61% of HIV-negative homosexual males), compared with 76% of HIV-positive women. These modest differences in gender-dependent infection rates suggest that the heightened risk of male homosexuals to anal cancer may result from a feature specific to receptive anal intercourse (e.g., trauma and/or the size of the viral inoculum) that collaborates with HIV and HPV infection.¹⁹² Consistent with this interpretation, at least some of the increased risk of male homosexuals to anal cancer seems to have predated the HIV era.⁴⁰⁶ The high risk of anal cancer among homosexual and bisexual men who are HIV positive has led some investigators to suggest routine screening of this population for anal squamous epithelial lesions.⁴⁵⁵

HPV INFECTIONS OF THE AERODIGESTIVE TRACT

Infections of the Oral Cavity

Benign HPV infections of the oral cavity occur commonly.^{209,481,597} They may be asymptomatic or associated with single or multiple lesions in any part of the oral cavity.

Genital-mucosal HPV types, especially HPV6, HPV11, and HPV16, have frequently been recovered from oral tissue. HPV is usually identified in at least one-half of papillomatous lesions in the oral cavity, but some lesions appear to be HPV-negative. HPV6 and HPV11 seem to be responsible for most benign HPV oral lesions, although HPV16 may also be found. Focal epithelial hyperplasia (FEH) is a well-defined clinical entity that occurs only in the oral mucosa. Its distribution is worldwide, but it is most prevalent in the indigenous populations of Central and South America and of Alaska and Greenland. In Greenlandic Eskimos, the prevalence in different localities varied between 7% and 36%. In contrast, the prevalence among Caucasian residents in the same localities was less than 1 in 300. Most infection is attributed to HPV13 or HPV32, two types that appear predominantly to infect the oral cavity. Maternal transmission of genital-mucosal types to newborns occurs, but its relevance to disease outside the oral cavity seems to be limited to recurrent respiratory papillomatosis, as discussed below.¹⁴⁴

Head and Neck Cancers

Cigarette smoking and alcohol consumption are two well-known risk factors for head and neck cancer. Although HPV does not appear to be involved in most cancers in the mouth (oral cavity),³⁶⁷ consistent data from several industrialized countries indicate that a subset of head and neck cancers are attributable to HPV infection.^{32,62,208,330,558} HPV16 accounts for about 90% of the HPV-positive tumors. Most of these HPV-associated cancers are located in the oropharynx, which includes the tonsils, tonsillar fossa, base of the tongue, and soft palate. It is not understood why the HPV-positive tumors preferentially develop in the oropharynx. In the United States, the incidence of these oropharyngeal cancers, which usually develop at a younger age than the HPV-negative cancers, increased more than threefold between 1988 and 2004 (Fig. 54.26).⁹⁵ If this trend continues, these tumors are predicted to account for more

HPV-positive cancers than cervical cancer, although the incidence of oral HPV infection is an order of magnitude lower than that of anogenital.^{209,239,333} About three-fourths of the patients with HPV-positive tumors are male, and most of the increased incidence is confined to white males. The decrease in tobacco use has been associated with a decreased incidence of HPV-negative oropharyngeal tumors. In the United States, HPV-positive tumors now account for more than two-thirds of the oropharyngeal cancers.

The behavioral risk factors for developing HPV-positive oropharyngeal cancer are similar to those for anogenital HPV-positive cancer.¹²⁴ A history of oral-genital sex is also an important risk factor. Some studies suggest that tobacco and alcohol do not increase the risk of HPV-positive tumors,¹²⁴ whereas others have reported they are associated with an increased risk for both HPV-positive and HPV-negative tumors.⁵⁵⁹ The HPV-positive tumors share many molecular features with those of HPV-positive anogenital tumors. Specifically, the oropharyngeal tumors usually have integrated HPV DNA that preferentially expresses E6 and E7, and their p53 and pRb genes are wild-type, and most of them express p16,^{10,288,341} in contrast to the HPV-negative tumors, which tend to have mutant p53 and to be p16-negative. Despite the similarities with HPV-positive anogenital cancers, there is thus far no clearly identifiable premalignant oropharyngeal lesion for HPV-positive tumors.

The HPV-positive oropharyngeal cancers carry a better prognosis than the HPV-negative ones, but cigarette smokers with an HPV-positive cancer have a poorer prognosis than nonsmokers.^{10,490} Blacks who develop oropharyngeal cancer tend to have a poor prognosis, which appears to be attributable to their very low incidence of HPV-positive tumors.⁵⁴⁶ The basis for this low incidence is unclear, as blacks are not resistant to HPV-positive anogenital tumors.

Recurrent Respiratory Papillomatosis (Laryngeal Papillomatosis)

Laryngeal papillomatosis is a rare condition the papillomas of which can severely compromise the airway, particularly in young children.^{204,298,348,554} Most lesions are caused by genital HPV types that are also associated with external genital warts, especially HPV types 6 and 11. The vocal cords of the larynx is the site most commonly affected, but papillomas can arise at other sites, such as the trachea, lungs, nose, and oral cavity, even without laryngeal involvement. Lesions can be single or multiple.

Symptomatic papillomas are generally treated surgically, but the recurrent nature of the disease means that periodic surgical treatment may be required. It is important to avoid the necessity of performing a tracheostomy in patients with RRP, because papillomas often grow along the tissues involved in the tracheostomy, resulting in severe morbidity.

Epidemiologic studies suggest at least two modes exist by which RRP develops.³⁴⁸ One primarily affects young children and the other when RRP is first diagnosed in older individuals (Fig. 54.27). RRP may occur at any age, but the risk of developing it decreases after the age of 5 years. In children younger than this age, a maternal history of genital warts is a risk factor for RRP. In a population-based study in Denmark, close to 1% of children whose mothers had a history of genital warts developed RRP, corresponding to a 231 times higher risk of RRP relative to women without a history of genital warts.⁵⁵⁵ First pregnancy and young age of the mother are associated with an increased

FIGURE 54.26. Increasing prevalence of human papillomavirus (HPV)-positive oropharyngeal cancers over time in the United States. (Adapted from Chaturvedi AK, Engels EA, Pfeiffer RM, et al. Human papillomavirus and rising oropharyngeal cancer incidence in the United States. *J Clin Oncol* 2011;29:4294–4301.)

FIGURE 54.27. Cumulative percentage of cases of recurrent respiratory papillomatosis (RRP) in the United States. RRP in patients up to 5 years of age has a strong maternal inheritance component. (Adapted from Mounts P, Shah KV. Respiratory papillomatosis: etiological relation to genital tract papillomaviruses. *Prog Med Virol* 1984;29:90–114.)

risk, whereas cesarean section carries a lower risk.⁵⁴⁷ HLA antigen class II polymorphism may also be a contributing factor.²⁰⁰ Most cases of RRP that arise in early childhood are probably attributable to intrapartum transmission of HPV. *In utero* transmission also occurs, but it is rare. A history of oral-genital sex may be a risk factor in adult RRP. Despite the low incidence of juvenile-onset RRP, it has been estimated that annual U.S. medical costs for managing this condition is \$150 million.³⁴⁸

Although HPV6 causes genital warts more frequently than HPV11, the reverse is true of RRP, and cases with HPV11 tend to be more severe than those associated with HPV6.^{298,487,661} Given the presumed single exposure to HPV during vaginal delivery, the long and variable latent period of up to 5 years for childhood RRP remains to be explained. One possible explanation could be that viral latency is established in a proportion of exposed neonates before they develop symptomatic infection; latency has been shown in the larynx of patients with RRP who are in remission.³⁹¹

RRP is associated with a low risk of spread to the bronchi and lungs, progression to severe dysplasia, and even to cancer.²⁰⁴ The risk of such progression is increased if the papillomas have been subjected to X-irradiation, which was a common treatment of RRP in the 1940s. In contrast to cervical cancer, HPV6 and HPV11 in RRP are clearly associated with severe dysplasia and cancer, with HPV11 predominating, although high-risk types such as HPV16 may sometimes be found in laryngeal cancer not associated with RRP.⁶⁴

HUMAN PAPILLOMAVIRUS AND THE NONGENITAL SKIN

Nongenital Skin Warts

Nongenital skin warts are benign papillomas that occur most commonly on the hands and feet, although they can arise in

almost any location.^{78,277} They occur frequently in older children and young adults,²³⁵ with some surveys of adolescents indicating a prevalence of at least 20%.³⁰⁹ PV can remain infectious in the environment for extended periods, and transmission via fomites can occur relatively commonly.²⁰³ Because of the apparent need for PV to infect basal cells at the time of inoculation, maceration of the skin may predispose to cutaneous infection. Multiple lesions are most common, and they can be distributed symmetrically or be unilateral. Lesions involving apposing areas of skin or mucous membrane, as occur frequently, probably develop by autoinoculation. Most infections are present for several months and regress spontaneously within 2 years, although some persist indefinitely.

Although not absolute, a reasonably good correlation is seen between the clinical lesion and the HPV type. HPV1, HPV2, HPV4, HPV27, HPV57, and HPV65 are usually associated with common warts and plantar warts, including mosaic warts, whereas HPV3, HPV10, HPV28, and HPV41 are found in flat warts. Butchers and meat handlers may have an unusually high prevalence of hand warts; HPV7 is found in most lesions. It is believed that the combination of maceration and trauma predispose these workers to the development of clinical lesions when they are exposed to this HPV type.⁴⁷⁹

Regression of lesions is thought to be mediated immunologically. When most lesions regress spontaneously, there may be a mild mononuclear cell infiltrate, although regression of flat warts can be associated with an erythematous reaction around the lesions in association with an intense inflammatory infiltrate. The lower incidence of warts in older individuals⁴⁷⁹ may imply that immune mechanisms have rendered them relatively resistant to infection.

Epidermodysplasia Verruciformis

Epidermodysplasia verruciformis is a rare disorder in which affected individuals have a unique susceptibility to cutaneous HPV infection.^{387,444} The warts usually develop in childhood, become widespread, do not tend to regress, and, in some instances, may progress to squamous cell cancers. Two predominant types of lesions are seen, which can occur in the same patient. Some lesions have the appearance of flat warts, whereas others are flat, scaly, red-brown macules. The flat warts are caused by the same HPV types that induce flat warts in the general population, usually HPV3 or HPV10. The scaly lesions are associated with a range of beta-HPV types, especially HPV5 and HPV8. Patients with EV are frequently infected with several HPV types.

About one-third of patients with EV will develop skin cancers in association with their lesions. Most of the malignant tumors remain local, but regional and distant metastases may occur. The risk of malignant progression is limited to the pityriasis-like lesions, which are the lesions that contain the EV types. HPV5 and HPV8 seem to be the most oncogenic, because most of the skin cancers contain one of these two types. The skin cancers usually develop on sun-exposed areas, implying that carcinoma develops in EV by a combination of infection by an oncogenic EV HPV type plus the cocarcinogenic effects of UV light. p53 mutations are common in EV-associated cancer,⁴⁴⁹ in contrast to the mucosal cancers associated with HPV.

EV occurs as an inherited disorder in approximately one-half of affected patients, and many families with EV have a

history of parental consanguinity. Inheritance has an autosomal recessive pattern in most affected families, although one family with apparent X-linked recessive inheritance has been reported, as has another with apparent genetic dominance (no history of parental consanguinity, and EV in father and son).⁴⁰⁰ The cases with autosomal recessive inheritance are genetically heterogeneous, as the condition in different families have been mapped to two distinct chromosomal loci, at 2p21-p24 and 17q25.⁴⁸⁹ Two adjacent novel genes (EVER1 and EVER2) with nonsense mutations in some EV families have been molecularly identified at the 17q25 locus.⁴⁸⁸

Patients with classic EV do not ordinarily display an increased susceptibility to clinical infection with other microbial agents, including the mucosal HPV types or those HPV types associated with common warts. Because many healthy individuals have been found to harbor EV-specific HPV types in normal skin, patients with EV are unusual in that these HPV types produce clinically apparent lesions. The lesions in patients with EV are resistant to usual treatment modalities. Global defects in cellular immune function can be demonstrated in most, but not all, patients with EV. In addition, acquired EV has been described in association with HIV infection,^{36,279} and clinical lesions associated with EV-specific HPV types have been described in some other immunosuppressed individuals. These include patients with a genetically defined subset of severe combined immunodeficiency disease³⁴²; some with common variable immunodeficiency syndrome^{342,641}; and a family with a T-cell defect attributable to a premature stop codon in the RHOH gene, a GTPase expressed predominantly in hematopoietic cells, which renders the patients susceptible to multiple infections, including clinical lesions attributable to beta-HPV.¹¹⁷

In familial classic EV, the genetic lesion is present in the cutaneous keratinocytes as well as the cells of the immune system. It is therefore difficult to infer unambiguously whether the susceptibility to clinical lesions in classic EV is attributable mainly to an epithelial cell defect, immune deficiency, or both.⁴⁴⁴ With acquired EV, by contrast, the defects have been limited to various types of immunodeficiency. This observation implies the development of acquired EV is attributable to immune defects that render the cutaneous keratinocytes permissible for the development of clinical lesions. Molecular analyses of the EVER genes, which interact with the zinc transporter ZnT-1,³⁵¹ do not yet permit a clear answer for classic EV. On the one hand, keratinocytes that are null for EVER2 grew faster than wild-type keratinocytes and had higher nuclear zinc levels.³⁵¹ On the other, compared with their expression in keratinocytes, the EVER genes are expressed at substantially higher levels in T cells, and T cells from EVER2 patients have elevated zinc levels and impaired T-cell activation.³⁵⁰

Nonmelanoma Skin Cancer

Nonmelanoma skin cancers (NMSCs), which are extremely common, are generally subdivided into basal cell carcinomas (BCCs) and squamous cell carcinomas (SCCs). They generally arise on exposed areas of skin, most commonly in light-skinned individuals. Sunlight exposure is a predominant risk factor, and tumors associated with sun exposure are usually locally invasive, but only rarely metastasize. The skin of immunosuppressed individuals is at high risk of developing warts as well as premalignant lesions and NMSCs, especially SCCs, on exposed areas.^{227,445}

The known oncogenic potential of at least some HPV types and the consistent finding of certain beta genus HPV types in SCCs associated with EV make HPV infection an attractive etiologic agent for at least some NMSCs in individuals who do not have EV.¹⁷⁶ Beta HPVs are known to encode candidate oncoproteins that can interfere with UV-induced apoptosis,²⁷⁸ which might allow keratinocytes with UV-induced mutations to survive and progress to carcinomas. Beta HPV DNA is frequently detected in SCCs using sensitive PCR-based detection methods, but it is also frequently detected in normal skin.^{58,482,548} Furthermore, the genome copy number is usually much less than one copy per tumor cell,⁶⁴⁸ in contrast to HPV-associated anogenital and oropharyngeal cancers. A recent study employing an unbiased analysis involving high-throughput sequencing of randomly primed mRNAs detected virtually no HPV transcripts in SCC specimens.¹⁹ Weak or no association was also observed in L1-based serologic assays for individual cutaneous HPV types,^{58,477} although an association with seropositivity to beta HPVs in aggregate was detected in some analyses.

Overall, the association between HPV infection and NMSCs must be considered weak at present, since continuous expression of predominant HPV types has not been as clearly identified in NMSCs as in EV-associated cancers or mucosal cancers associated with HPV. In addition, the HPV-positive tumors are not clinicopathologically distinct from the HPV-negative ones, in contrast to vulvar or oropharyngeal cancer. It remains formally possible that cutaneous HPVs induce SCCs but are not required for their maintenance,⁶⁴⁸ and there could be strong biological or immunological selection for their loss during progression. Alternatively, the detection of HPV DNA may be an epiphenomenon. This latter possibility needs to be seriously considered, because healthy skin often contains HPV DNA, especially of beta types,¹² and removal of the superficial layers of NMSC lesions has been reported to result in a drastic reduction in the proportion of HPV-positive lesions.¹⁸⁵

HUMAN IMMUNODEFICIENCY VIRUS AND HUMAN PAPILLOMAVIRUS INFECTIONS

The immune suppression resulting from HIV infection is associated with an increased susceptibility to infection by many other microbial agents. The risk of genital HPV infection may be particularly high for HIV-infected individuals because infection by both viruses is often acquired via sexual transmission, and it is well known that exposure to one sexually transmitted agent places an individual at higher risk for exposure to other sexually transmitted agents. Therefore, individuals at high risk for sexual exposure to HIV would tend to be at high risk for exposure to genital HPV infection.

It is well documented that cervical HPV infection is detected more frequently in HIV-positive women than in those who are HIV-negative; the infection is even more likely to persist, it is more likely to result in cytologic abnormalities, and a much greater risk is seen for high-grade dysplasia.^{451,591} In one prospective study of high-risk women in New York, cervical swabs taken at the initial examination detected HPV DNA approximately twice as frequently in HIV-positive women compared with HIV-negative women (56% versus 31%), and persistent infection was six times as frequent in the HIV-positive women (24% versus 4%).⁵⁹¹ Low-grade dysplasia

(CIN1) was about three times as frequent in HIV-positive women (13% versus 4%), whereas high-grade dysplasia was seven times more frequent (7% versus 1%). Low CD4 counts in HIV-positive women represent an independent risk factor. The rate of oral infection is also higher in HIV-positive individuals.²⁹

Consistent with the cervical findings, retrospective studies from New York reported that an unexpectedly high proportion of cervical cancers diagnosed in women younger 50 years of age were in HIV-positive women,³⁸⁶ leading the Centers for Disease Control and Prevention (CDC) in 1993 to designate cervical cancer as an acquired immunodeficiency syndrome (AIDS) case-defining illness. Analysis of large cohorts has confirmed that HIV infection places women at increased risk of developing cervical cancer.^{96,192,545} HIV infection represents a risk factor for other malignancies associated with HPV infection, including cancers of the vulva, penis, and anus.¹⁹² As noted, the relative risk for anal cancer is especially high for HIV-infected male homosexuals. HPV types with limited malignant potential in the HIV-negative population may be associated with aggressive tumors in HIV-positive patients.^{237,238}

In contrast to the inverse correlation between CD4 levels and the risk of HPV infection and dysplasia, the risk of invasive cancer may not be associated with low CD4 levels.²⁷⁵ In addition, highly active antiretroviral therapy (HAART) has been associated with only a modest reduction in HPV-associated dysplasia, and no reduction in HPV-associated cancers in most studies.^{104,134,275,413,450} EV lesions also appear to be resistant to HAART.²⁷⁹ These observations are in contrast to the substantial HAART-associated reduction in the incidence of Kaposi's sarcoma-associated herpesvirus (KSHV)-associated tumors and with Epstein-Barr virus (EBV)-associated non-Hodgkin's lymphoma.

Immunity

PVs typically induce persistent epithelial infection with little or no pathologic consequence to their host. This generally peaceful co-existence reflects a basic viral strategy of minimizing host cell damage and thereby the immune responses to its presence.¹⁸⁹ Although some infections, particularly with some species of the HPV beta genus, may persist lifelong in an occult fashion, most infections are cleared, or controlled to undetectable levels, in a span of months to years. Incident infection rates tend to decline with age after they peak, consistent with the acquisition of effective immunity. Both humoral and cellular immunity likely play a role in preventing, controlling, and/or clearing PV infection, so the virus has evolved mechanisms to evade both arms of the immune system.

The fact that PVs have evolved into hundreds of genotypes that are essentially distinct serotypes that cannot be effectively cross-neutralized by antibodies induced by natural infection strongly implies that such antibodies play an important role in virus-host interactions.⁶²⁶ It is unlikely that virion antibodies play a role in clearing infections because the virion proteins are not expressed on the surface of living cells, and so are not susceptible to known antibody-mediated mechanism of immune regression. However, neutralizing antibodies induced by infection likely play a role in preventing successive rounds of autoinoculation, reinfection from an external source, and perhaps spread to another host. The latter can be readily envisioned for genital mucosal infections, where the virions are shed into mucus that can also contain virion-neutralizing antibodies.⁴²⁸

Virion antibody responses have been best characterized for genital infections in women. They are generally not detected until months after initial infection, and the titers induced are modest.¹⁴³ Response may be somewhat more robust for genital wart types than high-risk types.⁸⁴ Many infections clear without the induction of a measurable antibody response. There is some disagreement in the literature over whether virion antibodies measured after natural infection can protect from reinfection.^{518,636} However, these studies are confounded by difficulties in distinguishing reinfection from reactivation of latent infection and in distinguishing low level of virion-specific from non-specific antibodies. It seems quite likely that women with higher than average virion antibody titers to mucosal types in their serum are afforded at least partial protection from type-specific reinfection.⁵¹⁸ Most adults are seropositive for L1 antibodies to one or more cutaneous HPVs, and the antibody responses tend to persist.¹³ The role of these antibodies in the natural history of cutaneous HPV infection is not well understood.

Substantial antibody responses to the early viral proteins are seldom detected, except in the case of invasive cancers. In cervical cancers, responses to E6 and/or E7 are detected in approximately half of the patients.⁶³⁷ Contributing factors in the weak humoral responses to viral infection include the absence of viremia, the low level or absence of the viral proteins in the basal layers of the epithelium, the release of the virions onto external skin or mucosal surfaces, and the limited inflammation induced by the superficial nonlytic infections. Low intrinsic immunogenicity of the viral proteins does not seem to play a role. For instance, the capsids can be highly immunogenic when exposed to the systemic immune system, as exemplified by the VLP vaccine studies discussed below.

Adaptive cell-mediated immunity likely plays a key role in inducing the regression of PV-induced lesions and preventing reactivation of latent infection. When multiple warts are present, it is not uncommon for removal of one wart to be followed by the regression of others, suggesting a systemic immunologic response triggered by release of antigen from the treated wart is responsible for regression. Patients with conditions that affect T-cell immunity, such as pregnancy, immunosuppressive chemotherapy, or HIV infection, are at increased risk of HPV infection that persists, as well as an increased risk of cervical cancer.^{18,133,179,192} Likely, at least some of these infections represent reactivation of latent infection, rather than being secondary to new exogenous exposure. Even benign HPV infections in immunosuppressed patients are notoriously difficult to treat, and reduction of the immune suppression may be associated with the spontaneous improvement of the HPV-induced lesions.

The immune effectors mechanisms and viral antigens involved in lesion regression and prevention of reactivation are not well defined. Descriptive studies of cell-mediated immune responses have mostly focused on genital infections in women. Until recently, most studies have evaluated systemic responses, whereas local mucosal responses are likely to be the critical determinants. Modest systemic CD4+ and CD8+ cytotoxic T-cell (CTL) responses to E6 and E7 are often detected in women with previous or current cervical HPV16 infections.^{170,425,426} Interestingly, failure to clear infection was associated with lack of induction of CTL to E6, but not E7.⁴²⁵ In women with HPV16-associated CIN1, CD4 T-cell responses to E2 and E6 were most frequently detected, and Th1-type CD4 responses to

these viral proteins are also most frequently detected in women without infection.^{131,650,670} In a prospective study, the presence of HPV16 E2–specific responses in an interferon-gamma enzyme-linked immunosorbent spot (ELISPOT) assay correlated with lack of progression of HPV16–associated lesions.⁶⁷⁰

The local tissue responses in regressing cervical lesions were recently characterized. Granzyme B–expressing CD8 T cells predominated, and a higher ratio of CD8 and Foxp3–negative CD4 cells over CD4 Foxp3–positive (regulatory) CD4 T cells was detected.^{447,669} In contrast, the infiltrates in persistent and progressing lesions were associated with a suppressive environment, including granzyme B–negative and PD-1–expressing T cells (a sign of exhaustion) and high numbers of Foxp3+ Tregs, and macrophages.^{236,276,297} Studies in E7 transgenic mice suggest that persistent epithelial expression of the viral proteins in a non-inflammatory setting can actively tolerize CTL precursors.¹⁴⁷

In a prospective study of high-grade HPV16–associated CIN lesions, infiltration of CD8+ T cells into the epithelium was observed in lesions destined to regress.⁶²⁰ They were excluded from the epithelium in lesions that persisted, although infiltrates in the submucosa adjacent to the lesions were frequently observed. The results suggest that dysregulation of T-cell trafficking and/or adhesion plays a role in viral immune evasion. Finally, loss of epidermal Langerhans cells (the primary professional antigen presenting cell in the epidermis) has been documented in mucosal and cutaneous lesions caused by HPVs of the alpha, gamma, mu, and nu genera, which may help to create an environment permissive for viral persistence.³⁶⁰

The induction of cancers by certain PV types is an aberration to both the host and the virus, since cancers are too dedifferentiated to produce virions. Therefore, carcinogenesis plays essentially no role in the evolution of papillomavirus immunobiology. However, immune evasion during carcinogenic progression is of obvious clinical interest. HPV-induced cancer and high-grade dysplasias are genetically unstable and therefore readily able to evolve to evade immune recognition. The majority of cervical cancer and CIN3 lesions have defects in MHC class I presentation, generally through downregulation of specific class I alleles or defects in antigen processing for class I presentation.^{53,323} Therefore, it appears that most tumors have undergone strong selection for escape from CD8+–mediated immune responses.

Given that PVs have evolved to persistently infect their host, it is not surprising that their early proteins have specific activities involved in inhibiting immune recognition and/or clearance. The E5 of several PV types, including BPV1, BPV4, HPV2, HPV6, and HPV16, has been shown to downregulate the expression of cell surface MHC class I molecules, which can reduce recognition of E5–expressing cells by HPV-specific CD8+ T cells.⁸¹ In addition, HPV16 E5 was recently been shown to increase cell surface GM1 ganglioside.⁵⁹³ Because gangliosides are known to inhibit killing by CTLs, their upregulation by E5 may be another mechanism of preventing immune clearance.

Type I interferons are involved in control of most viral infections, by direct inhibition of virus replication and by aiding in the induction of adaptive immune responses.³⁷⁶ PV E6 and E7 genes blunt type I interferon responses by several specific mechanisms. HPV16 E6 binds interferon regulatory factor-3 (IRF-3) and in so doing inhibits its ability to act as a transcriptional transactivator for interferon gene expression in response to viral infection.⁵¹⁰ Viral genes also disrupt inter-

feron signaling. HPV16 E7 inhibits induction of interferon alpha inducible genes by specifically disrupting the interferon-stimulated gene factor 3 complex (ISGF3).²⁵ HPV18 E6, but not HPV11 E6, was also shown to interfere with interferon alpha activity by binding Tyk2, a molecule involved in interferon alpha receptor 1 signaling.³⁶³ Expression of E6 and E7 of high-risk types can also downregulate expression of TLR9, the pattern recognition receptor of the innate immune system that recognizes CpG oligonucleotides, and IL-8, a potent chemoattractant of T cells and neutrophils.^{241,259} The E6 and E7 of both low- and high-risk types inhibit transcription of MIP3 alpha, a potent chemoattractant of Langerhans's cells.²²⁹

DIAGNOSIS AND TREATMENT

Human Papillomavirus Diagnosis

The approach used for the diagnosis of HPV infection may depend to a considerable degree on the underlying goal for making the diagnosis. These goals can include a determination of whether HPV is present, whether an active infection is present, which HPV type(s) is associated with the infection, and the degree of cellular atypia associated with the infection. If routine *in vitro* propagation of HPV from clinical samples were available, its isolation from productive infections, theoretically, would be possible. No such assays exist, however, and their utility would be limited by the fact that high-grade dysplasias and cancers do not produce infectious virus. The potential use of virus-specific antisera in tissue sections or extracts is limited by analogous considerations. L1 and E4 proteins can be expressed at high levels in productive lesions, but not in high-grade dysplasias and cancers.¹⁵¹ The expression of E6 or E7 proteins should be higher in advanced lesions, but clinical utility has not yet been validated.⁵⁴⁰

Serologic assays in an enzyme-linked immunosorbent assay (ELISA) format that monitor the antibody response to L1 in VLPs may have utility for population-based research studies,^{84,143,272} and a high-throughput neutralization assay with comparable sensitivity has also been developed.⁴⁶¹ However, these assays, which measure both current and past infection, are not sufficiently sensitive or specific to be used for routine clinical diagnosis. Invasive cervical cancers, but not the premalignant lesions, are associated with serum antibodies against E6 and E7.⁴⁰⁹ Most patients with HPV16–positive oropharyngeal cancer have detectable anti-E6 and/or E7 serum antibodies.⁵⁵⁷

On the other hand, sensitive, reproducible, and robust molecular assays have been developed to detect HPV DNA and RNA in cervical swabs and biopsy samples, several of which have been approved by the FDA.^{272,291,437,532,601} Approaches for such assays include PCR consensus primers (or alternative amplification systems) that can be used in conjunction with a reverse line blot for specific hybridization, synthetic RNA probes that capture viral DNA, real time PCR, and microarrays. Some assays detect L1 DNA sequences, whereas others detect E6 or E7 DNA or RNA. The most sensitive tests may be preferred if the goal is to detect as many infections as possible.

For cervical cancer screening, the goal is to maximize identification of those infections associated with high-grade abnormalities (true positives), which usually should be treated, while excluding as many infections with low-grade abnormalities (false positives) as possible, which should not be treated

because most are destined to clear spontaneously.^{300,499,509,528} Achieving this balance means that the signal used for screening must exceed a certain threshold, in order to reduce the number of false positives, while still identifying most true positives. Some assays use a cocktail that can detect more than 10 high-risk HPV types, whereas other assays are type-specific. The greater oncogenicity of HPV16, and HPV18 to a lesser extent, may also argue for the importance of knowing whether a patient is infected with either of these HPV types.

Other biomarkers may also have the potential, as stand-alone or ancillary tests, to contribute to distinguishing between those HPV infections associated with precancer and those that are not. The most advanced is p16, which is elevated in response to the inactivation of pRb by E7 from high-risk viruses.^{503,520,644} Methylated viral DNA or methylation of specific cellular genes,^{168,414} as well as other markers, are also being evaluated.^{569,654} Although population-wide screening efforts are directed toward cervical cancer, the high risk of anal cancer among men who have sex with men has led some investigators to consider screening high-risk populations for this cancer.⁴⁵⁰

Since its introduction in the 1950s, cytologic screening with Pap smears, the main goal of which is to prevent cancer by identifying premalignant lesions that can then be treated, has been the basis for the substantial reduction in the incidence of and mortality from cervical cancer. The greater sensitivity of HPV-based assays gives them several advantages over cytology. These include the greater negative predictive value of HPV testing, which can permit longer intervals between screens, and the greater sensitivity of HPV testing in detecting cervical adenocarcinoma precursors, which cytologic screening tends to miss.^{300,499,509,532} In the United States, cervical cancer screening guidelines now recommend cytology-based screening every 3 years for women 21 to 65 years of age or co-testing with cytology and a U.S. Food and Drug Administration (FDA)-approved HPV test every 5 years for women 30–65.⁵²¹ HPV testing is also recommended for women with equivocal (ASCUS) Pap smears. Screening only by cytology is recommended for women younger than 30 because of their high prevalence of HPV infection without severe dysplasia, together with the likelihood that most infections in these young women will clear spontaneously. Primary HPV-based screening has been initiated elsewhere,⁴⁹⁹ and it seems likely that the United States will also make this shift in the future, especially if there is high uptake of the preventive HPV vaccine.⁵

In the developing world, the cost of cytologic screening has been too high for implementation of population-wide cervical cancer screening. The development of inexpensive HPV tests that are suitable for screening may soon make it cost-effective for population-wide screening in developing nations.⁴⁸⁶ The limited resources in developing countries make it likely that women there could not be screened more than three times in a lifetime. Under those circumstances, HPV testing can reduce cervical cancer mortality in women older than 30 years of age, whereas the lower sensitivity of cytology (or visualization of cervical lesions with acetic acid) limit their effectiveness in such settings.⁵¹⁹

Treatment

In cervical HPV infection, treatment of low-grade dysplasia is not usually warranted, given that most of these lesions will clear spontaneously. High-grade dysplasias represent precancerous lesions that are unlikely to resolve spontaneously, and their

treatment is recommended to prevent cervical cancer. Depending on the setting, treatment of cervical dysplasia can be surgical, with cryotherapy, via loop electrosurgical excision repair, or by laser. In most instances, this approach prevents cervical cancer. HPV testing can be used in this setting, because most successfully treated cases become negative for HPV DNA, whereas incompletely treated cases may remain positive.⁶⁹⁶ Cervical cancer is treated by surgery, radiotherapy, and chemotherapy, with early stage tumors having a better prognosis than more advanced tumors.^{392,504}

Given what is now known about key molecular events in HPV infection, considerable potential exists for developing antiviral therapies against HPV in addition to immunotherapy.^{187,577,581,665} An antiviral that targeted a molecular activity common to all HPV types, or at least to a large number of them, such as the interaction between high-risk E6 and E6AP, might have the theoretic advantage of being active against multiple types, in contrast to the predominantly type-specificity of most viral antigens. Antisense and ribozyme approaches may also have some potential, but their activity is likely to be type-specific.

Two immunomodulatory agents, interferon and imiquimod, are approved for use against genital warts, although destructive therapy is often used to treat these lesions. In placebo-controlled trials, intralesional and parenteral interferon therapy was active against refractory genital warts,¹⁰⁹ whereas topical imiquimod, which activates TLR7 and induces interferon and other cytokines, was also effective.^{199,220,680} Neither agent, however, cures more than two-thirds of treated patients.

Interferon therapy of recurrent respiratory papillomatosis has been less successful than that of genital warts, and surgery remains the principal therapeutic modality, with only a few patients appearing to derive therapeutic benefit. Controlled trial results with antivirals have been disappointing.^{89,424,550}

As with other HPV infections, no specific antiviral therapy is available for nongenital warts. Most treatments are aimed at destroying the lesional tissue while causing as little long-term damage as possible to the surrounding normal tissue. No treatment will cure all warts, which has led to the wide range of therapies. At least partial regression can be obtained with many therapies, but even complete clearance that is then followed by recurrence is usually of limited clinical value. Traditional therapies include topical application of caustic agents (e.g., salicylic acid, podophyllin), cryotherapy, inhibitors of DNA synthesis (5-fluorouracil), and surgical therapy or laser treatment.

PREVENTION

Interruption of Transmission

As noted above, the epidemiology of various forms of HPV infection can differ drastically. Therefore, approaches to control genital HPV infection would be distinct from those to control nongenital infections. Pap smear screening can prevent most cervical cancers, which represent the most serious public health consequence of HPV infection but presumably do not have appreciable impact on transmission.

Public health efforts that can prevent other sexually transmitted infections should, in principle, also be effective in preventing genital HPV infection. Indeed, decreased sexual promiscuity on the part of both sexual partners should reduce the likelihood of exposure to genital HPV. In the absence of

specific treatment that would eradicate genital infections, investigation of sexual partners of infected individuals would not be expected to have much impact on HPV transmission, although it may help identify infected individuals who otherwise might not realize that they are infected.

Although HPV can infect genital areas that are not covered by condoms, condom use may reduce the incidence of genital HPV infection. Consistent with this possibility, several studies in men have reported that condom use is associated with fewer genital HPV infections and a shorter duration of infection in those men who were infected.^{434,460} For women, a meta-analysis found no consistent evidence that condom use in their sexual partners reduced the risk of acquisition of cervical HPV infection, but it was associated with some protection against genital warts, CIN2, CIN3, and cervical cancer.³⁸⁸ However, in a prospective study, consistent condom use by their partners reduced cervicovaginal HPV infection in young women by two-thirds.⁶⁶⁶ As another possible intervention measure, circumcision of adult men was shown to reduce their acquisition of high-risk HPV infection by almost one-half after 2 years.⁶¹⁷

HPV topical microbicides are under active evaluation. Carrageenan, a complex polysaccharide derived from red algae, is a potent inhibitor of HPV infection of cultured cells. In vivo, it mitigates the potentiating effects on cervicovaginal HPV pseudovirus infection induced by nonoxynol 9—containing over-the-counter spermicides and Pap smear collection in mouse and macaque models.^{76,500,501} Carrageenans are widely used in food and cosmetic products and are the main gelling agent in some over-the-counter sexual lubricants. In a trial designed to test the efficacy of a carrageenan gel in prevention of HIV infection, some protection against HPV infection at the exit visit was observed, but only in the subgroup that was most compliant with use instructions.³⁹⁰ Clinical trials designed to formally evaluate carrageenan gels as HPV microbicides will soon commence.⁴⁶⁵ Epidemiologic findings, discussed earlier, suggest that most cases of juvenile-onset RRP that arise in infants and young children have been transmitted from exposure to the mother's HPV during vaginal delivery. This hypothesis raises the possibility that the use of cesarean section for the delivery of infants of mothers with known genital HPV infection would reduce the risk of HPV exposure. The incidence of genital HPV infection is high, however, whereas that of RRP is low, which means that many cesarean sections would be needed to prevent each case of RRP. These considerations suggest that the morbidity and mortality risk to the mother associated with cesarean section may, in most situations, be greater than the risk of RRP to the baby, which has led some investigators to argue against the widespread use of this procedure to prevent RRP. However, because the risk of RRP is greater for younger women and for first pregnancies, a subset of HPV-positive women may exist for whom the cost-to-benefit analysis might favor cesarean section.⁵⁴⁷ HPV vaccination with Gardasil (discussed below) or use of an HPV topical microbicide might be effective interventions to reduce the rate of RRP, although it would be difficult to demonstrate their effectiveness in a clinical trial because of its low incidence.

Prophylactic Vaccination

The important public health consequences of genital HPV infection make it highly desirable to develop an effective vac-

cine against those HPV infections associated with cancer, especially cervical cancer. Vaccines to prevent oncogenic HPV infections could potentially prevent the full spectrum of HPV-associated cancers, in contrast to current screening programs that are only effective at preventing squamous carcinoma of the cervix. Although it would be ideal if a vaccine could both treat established infection and induce long-term protection against incident infection, efforts to develop therapeutic vaccines, have thus far had limited success in human clinical trials. Most HPV studies have focused on prophylactic vaccine strategies, because of the success of preventive vaccines against other viral diseases.⁴⁷⁸

Early studies with CRPV indicated that systemic injection with papilloma suspensions that did not produce detectable infection could induce serum neutralizing antibodies and protect rabbits against high-dose cutaneous viral challenge.⁵⁵² Intradermal injection of a vaccine composed of formalin-inactivated COPV virions was shown to protect against COPV-induced oral lesions under field conditions.³³ This result demonstrated that systemic immunization can induce protective immunity against natural transmission of a mucosal PV infection. However, the viral determinant(s) that conferred protection were not definitively identified in these studies.

The inability to produce preparative amounts of HPV virions, together with the presence of oncogenes in the viral genomes, suggested that a subunit vaccine would be a preferred approach. A key observation in the development of a prophylactic vaccine was finding that L1 can self-assemble into VLPs, which are empty capsids that closely resemble those of authentic virions morphologically and immunologically.^{234,313,511} As with authentic virions, L1 VLPs were highly immunogenic, inducing high titers of neutralizing antibodies that were conformation-dependent and type-restricted.³⁸¹ In several animal PV models, systemic immunization with L1 VLPs induced strong protection against high-dose experimental challenge by the homologous virus.^{68,108,312,595} Protection was type-specific, of long duration, and could be passively transferred with immune immunoglobulin G (IgG), implying that neutralizing antibodies were sufficient for protection. L2 also contains neutralization epitopes, but they are not exposed in the context of the mature virion.⁵³⁴ Therefore, although co-expression of L1 and L2 in cells results in L1/L2 VLPs, these VLPs were neither more immunogenic nor more protective than L1 VLP.⁶⁸ Human trials, therefore, went forward with L1 VLPs, with the main focus on HPV16 and HPV18, the two most oncogenic HPV types. Despite the excellent results with the preclinical models, none represented a genital infection, and it was unclear how relevant these models would be to genital infection under natural conditions. In addition, most vaccines protect against systemic infection that has a viremic phase, which exposes the virus in contact with antibodies in the blood, whereas HPV induces an infection that spreads locally.

Two commercial prophylactic HPV vaccines have been developed. GlaxoSmithKline's Cervarix is a bivalent vaccine composed of L1 VLPs of HPV16 and HPV18, whereas Merck's Gardasil is a quadrivalent vaccine composed of L1 VLPs of HPV6, -11, -16, and -18. In addition to their valency, the two vaccines differ in production system, adjuvant, and recommended injection schedule (Table 54.7). Both vaccines were generally safe and able to consistently induce high titers

TABLE 54.7 Characteristics of HPV VLP Vaccines

	Cervarix	Gardasil
Manufacturer	GlaxoSmithKline	Merck
VLP Types	HPV16/18	HPV6/11/16/18
Dose of L1 Protein	20/20 µg	20/40/40/20 µg
Producer Cells	<i>Trichopulsia ni</i> (Hi 5) insect cell line infected with L1 recombinant baculovirus	<i>Saccharomyces cerevisiae</i> (Baker's yeast) expressing L1
Adjuvant	500 µg aluminum hydroxide, 50 µg 3-O-deacylated-4'-monophosphoryl lipid A	225 µg aluminum hydroxyphosphate sulfate
Injection Schedule	0, 1, 6 months	0, 2, 6 months

Gardasil® (Merck & Co., Whitehouse Station, NJ USA)

Cervarix® (GlaxoSmithKline Biologicals, Rixensart, Belgium)

HPV, human papillomavirus; VLP, virus-like particle.

of capsid-reactive antibodies in early phase trials.⁵³³ In phase III clinical trials of young women, both vaccines were also highly effective at preventing acquisition of cervical infection and low- and high-grade CIN caused by the types targeted by the vaccine (Table 54.8). These results have led to worldwide licensure of the two vaccines for prevention of CIN and cervical cancer caused by the vaccine-targeted types. Remarkably, Cervarix was recently shown to induce a high level of protection against persistent cervical infection 4 years postvaccination, even after administration of only one or two doses of the vaccine.³³² Both vaccines also induced a modest degree of protection against cervical infection caused by specific nonvaccine types closely related to HPV16 or -18. For instance, both vaccines induced partial protection against persistent infection by HPV31. Cervarix, but not Gardasil, induced significant protection against HPV45, and neither vaccine protected significantly against HPV35 or -58.^{72,248,656}

Gardasil was also highly effective at preventing genital warts, and vulvar and vaginal intraepithelial neoplasia, and it has been licensed for these indications^{145,317} (Table 54.8).

Cervarix was not evaluated for these end-points, probably because it does not target HPV6 and HPV11, the types that cause most genital warts. Neither vaccine induced significant clearance of established infections or regression of established lesions, and so they are not licensed for treatment of HPV infection or disease.^{195,250}

Prophylactic protection by the two vaccines against vaccine-targeted types does not appear to be waning in the more than 5 years since initiation of the VLP vaccine trials. Neutralizing antibody titers induced by the vaccines have remained essentially stable, and above the levels induced by natural infection, since the second year postvaccination period, supporting optimistic projections for long-term, perhaps lifelong, protection without the need for booster immunizations.^{507,514} However, cross-neutralizing titers against related types, when they are detected, are much lower than the titers against the vaccine-targeted types,³⁰⁴ and there are indications that protection against these types may wane over time.⁵⁰⁷

Gardasil was also tested for efficacy in men. Strong protection from genital warts was documented²¹⁴ (Table 54.8).

TABLE 54.8 Four-Year Efficacy of HPV VLP Vaccines Against Vaccine Targeted Types in According to Protocol Analyses of Phase III Clinical Trial

Study	Vaccine	Sex/age	End point	Efficacy	95% CI	Reference
PATRICA	Cervarix	Females 15–25	CIN2+	94.9%	87.7–98.4	(359)
FUTURE I/II	Gardasil	Females 15–26	CIN2+	100%	94.7–100	(317)
FUTURE I/II	Gardasil	Females 15–26	VIN2+/ValN2+	100%	82.6–100	(317)
FUTURE I/II	Gardasil	Females 15–26	Genital Warts	99.0%	96.2–99.9	(145)
CVT	Cervarix	Female 18–25	6-Month Persist. Infect.	90.9%	82.0–95.9	(248)
CVT	Cervarix	Females 18–25	Anal Infection at Exit	83.6% ^a	66.7–92.8	(332)
Merck 020	Gardasil	Males 16–26	Genital Warts	89.4%	65.5–97.9	(214)
Merck 020	Gardasil	Males 16–26	6-Month Persist. Infect.	85.6%	73.4–92.9	(214)
Merck 020	Gardasil	Males 16–26	AIN2+	74.9%	8.8–95.4	(452)

95% CI, Ninety-five percent confidence interval; PATRICIA, Papilloma TRial against Cancer In young Adults; FUTURE, Females United To Unilaterally Reduce Endo/Ectocervical Disease; CVT, Costa Rica Vaccine Trial; CIN2+, Cervical Intraepithelial Neoplasia grade 2 or worse; VIN2+, Vulvar Intraepithelial Neoplasia grade 2 or worse; ValN2+, Vaginal Intraepithelial Neoplasia grade 2 or worse.

^aSubjects were cervical HPV-16/-18 DNA negative at entry but anal HPV not evaluated at entry.

Relatively few penile intraepithelial lesions were detected in the trials, so the trial was unable to critically evaluate this end-point. The subset of the men who had sex with men was concurrently enrolled in a study of anal infection and anal intraepithelial neoplasia (AIN).⁴⁵² Excellent protection against vaccine type-related anal infection and AIN was observed (Table 54.8). The findings have led to licensure for these indications and for prevention of AIN and anal cancer in the United States, but not in Europe. U.S. licensure was extended to anal neoplasia in women based on the argument that AIN is indistinguishable in the two sexes. Although Cervarix has not been evaluated for prevention of AIN in either sex, it was shown to significantly reduce the prevalence of anal HPV infection at the end of a 4-year trial in young women.³³¹

The above trials were conducted in young women and men ages 15 to 26 years. Immunobridging studies were used to extend licensure to 9 to 14 year olds. Antibody responses to both vaccines were significantly higher (two- to threefold) in younger than in the older age groups.^{47,463} The higher responses in children led to a comparison of two- and three-dose vaccination protocols. For both vaccines, the antibody responses of children after two doses given 6 months apart was not inferior to the responses of young adults to three doses given according to the recommended schedules (Table 54.7).^{327,508} These findings have led some jurisdictions to initiate two-dose vaccination programs in children, with ongoing assessment of the need for administering a third dose.

Although highly immunogenic, both vaccines were well tolerated in both sexes. The primary side effects attributable to the vaccines were short-term pain, swelling, and erythema at injection site and low-grade fever and/or headache.^{214,243,466,538} In post-licensure studies, no pattern of serious adverse events has been associated with vaccination, except for rare anaphylactic reactions at rates comparable to that of other vaccines.^{199a}

Neutralizing antibodies are believed to be the primary, if not exclusive, immune effectors for the VLP vaccines, although a formal immune correlate of protection has not been determined. In part, this shortcoming is due to the remarkably small numbers of vaccine failures to date and the inability to definitively distinguish incident infection from emergence or reactivation of infections present at the time of vaccination. Antibodies induced by systemic VLP vaccination could reach the anogenital sites of infection by two mechanisms. One mechanism is transudation of serum IgG, which is especially pronounced at the cervix.⁴²⁸ Alternatively, systemic antibodies could be directly exudated at the site of trauma required for initiating infection.⁵⁰⁰ The second mechanism appears to be fully able to prevent infection, since strong protection was observed against genital warts on external genitalia sites, not normally exposed to transudated antibodies in mucus. In a mouse cervicovaginal challenge model, VLP-induced antibodies were shown to protect from keratinocyte infection by two distinct mechanisms.¹²⁸ At high concentrations, the antibodies prevented binding of the capsids to the basement membrane of the cervicovaginal epithelium. At lower concentrations that were nonetheless effective at preventing infection, the capsids were able to bind the basement membrane and undergo the conformational change that exposes L2 N-terminal epitopes. However, they were subsequently unable to stably associate with the

cervicovaginal keratinocytes, suggesting that lower antibody occupancy is needed to prevent capsid binding to the keratinocyte surface receptor than binding to the heparan sulfate proteoglycans of the basement membrane.

Since their initial approval in 2006, Cervarix and Gardasil have been licensed in more than 100 countries. However, they have been introduced into the national vaccination programs of only about 30 countries, mostly in the most developed ones because of the high cost of the vaccines and the implementation programs. National programs are mostly centered on vaccination of preadolescent or adolescent girls, ages 9 to 15 years, since most HPV-associated cancers occur in women,⁹⁴ genital HPV infections are often acquired soon after initiating sexual activity, and children responded better than adults to the vaccines. However, the recent evidence that Gardasil protects young men from genital warts and anal cancer precursors has provided additional support for considering male vaccination programs.

Australia was one of the first countries to achieve at least 70% coverage of adolescent girls, in this case with Gardasil, and is the first country to report public health impact of an HPV vaccination program. Remarkably, in a large sexual health center between 2007/2008 and 2010/2011, the number of genital wart cases in women and heterosexual men under 21 years old decreased by 90%, despite low coverage rates in boys.⁴⁹⁵ No decline was observed in women or men older than 29 years old. In another study involving a cervical cytology registry, the incidence rates of high-grade CIN in women younger than 18 years, but not older age groups, decreased by almost half within 3 years of implementation of the vaccination program.⁷¹

Virus Release

Perspectives

Adenoviruses were first isolated and characterized in 1953 by two groups who were searching for the etiologic agents of acute respiratory infections.^{134,283} The two isolated viruses were related and named *adenoviruses*, after the original tissue (adenoids) in which they were discovered. Human adenoviruses are responsible for only a small portion of acute respiratory morbidity in the general population and for about 5% to 10% of respiratory illness in children. But they can be responsible for epidemic outbreaks in nursing homes and among military recruits.¹⁷⁴ Oral administration of enteric-coated live human adenovirus (HAdV) species B types 4 and 7, the serotypes responsible for most outbreaks among military recruits, was introduced in the 1970s and was an effective vaccine for this population. But cessation of vaccine production in 1998 led to a resumption of adenovirus-associated respiratory illness at US military training centers,^{153,221} resulting in severe pneumonia and one death from HAdV species B type 14.³³⁰ Consequently, there is a renewed effort to produce adenovirus vaccines.^{166,204}

More than 100 members of the adenovirus group have been identified that infect a wide range of vertebrate hosts. All of these viruses contain a linear, double-stranded DNA (dsDNA) genome encapsidated in an icosahedral protein shell with fiber proteins of varying lengths extending from the vertices of the icosahedron that bind to receptors on host-cell surfaces through a terminal globular domain.

In humans, besides respiratory disease, adenoviruses cause conjunctivitis²⁴² and infantile gastroenteritis.⁹ In immunocompetent patients, adenoviruses usually cause a mild, self-limiting acute infection. However, in neonates and immunosuppressed patients, including patients with AIDS, adenoviruses can cause fulminant fatal pneumonia, hepatitis, and/or encephalitis.^{192,331}

Laboratory diagnosis is most rapidly done by polymerase chain reaction (PCR)-based assays.^{161,191}

In 1962, Trentin and colleagues³⁴² made a seminal discovery: human adenovirus type 12 induces malignant tumors after inoculation into newborn hamsters. This was the first time that a human virus was discovered to be oncogenic. No epidemiologic evidence has been reported linking adenoviruses with malignant disease in humans; extensive searches have generally failed to find adenovirus nucleic acids in human tumors.²⁰⁸ While in one recent study HAdV DNA was detected in >50% of pediatric central nervous system (CNS) tumors by PCR, it was also detected in normal CNS tissue from the same patients.¹⁷¹ Thus, the CNS may be a common site of latent, persistent adenovirus infection in children. While there is as yet little evidence that adenoviruses contribute to the etiology of human tumors, the ability to induce tumors in animals and to transform cultured primary cells established adenovirus as an important model system for probing the mechanisms of oncogenesis.

As the interest in adenoviruses as tumor viruses intensified, their virtues as an experimental system became evident. The prototype human adenoviruses are easily propagated to produce high-titer stocks, and they initiate synchronous infections of established cell lines. Further, the viral genome is readily manipulated, facilitating the study of adenovirus gene functions by directed mutational analysis. Studies of adenovirus-infected cells have made numerous contributions to our understanding of viral and cellular gene expression and regulation, DNA replication, cell-cycle control, and cellular growth regulation. Perhaps the most recognized contribution of the adenovirus system to modern biology was the discovery of messenger RNA (mRNA) splicing.^{24,53} Today, the utility of adenovirus as a vector for gene therapy is the subject of intense exploration. This chapter overviews the structure of the adenovirus particle, the adenovirus replication cycle in human cells, and its interactions with host cells and host organisms.

CLASSIFICATION

Adenoviridae have been isolated only from vertebrates—however from every major class from fish to mammals. Bioinformatic analysis of genome sequences⁷¹ indicate four major lineages corresponding to four genera: *Mastadenovirus*, isolated from mammals, including all human adenoviruses; *Aviadenovirus*, isolated from birds; *Atadenovirus*, so named because of their unusually high A+T content, isolated from reptiles, birds, a marsupial and mammals; and *Siadenovirus*, isolated from a reptile and birds. Fifty-six human adenovirus types have been recognized and are classified into seven species (A–G) on the basis of

TABLE 55.1 Classification Schemes for Human Adenoviruses (HAdVs, Genus *Mastadenovirus*)

Species	Hemagglutination Groups	Types	Oncogenic potential		% GC	Associated disease
			Tumors in animals	Transformation in cell culture		
HAdV-A	IV (little or none)	12, 18, 31	High	Positive	46–47	Cryptic enteric infection
HAdV-B	I (complete for monkey erythrocytes)	3, 7, 11, 14, 16, 21, 34, 35, 50	Moderate	Positive	49–51	Conjunctivitis Acute respiratory disease Hemorrhagic cystitis Central nervous system Endemic infection Respiratory symptoms
HAdV-C	II (partial for rat erythrocytes)	1, 2, 5, 6	Low or none	Positive	55	Keratoconjunctivitis in immunocompromised and AIDS patients
HAdV-D	III (complete for rat erythrocytes)	8, 9, 10, 13, 15, 17, 19, 20, 22–30, 32, 33, 36–39, 42–49, 51, 53, 54	Low or none (mammary tumors)	Positive	55–57	
HAdV-E	III	4	Low or none	Positive	58	Conjunctivitis Acute respiratory disease
HAdV-F	III	40, 41	Unknown	Negative	51	Infantile diarrhea
HAdV-G	Unknown	52	Unknown	Unknown	55	Gastroenteritis

serology, hemagglutination, oncogenicity in rodents, transformation of cultured primary cells, and genome sequencing^{152,280}

(Table 55.1). A proposal has been made recently for systematically naming human adenovirus types (superseding the term “serotype”) based on genome DNA sequences.¹² Types are to be defined by the amino acid sequence of the major capsid protein hexon, which contains the major neutralizing epitopes. These same authors have proposed that intertypic human adenovirus recombinants be designated by the identity of the hexon gene (*H*) and that of the fiber gene (*F*) encoding the second most important neutralizing epitope. For example, HAdV-H7/F3 will designate a virus with a type 7 hexon and a type 3 fiber.¹² This parsimonious nomenclature makes it unnecessary to assign a new adenovirus type number to each new recombinant between previously established types that have been isolated from patients apparently infected simultaneously with two or more types in military recruiting centers and nursing homes.

VIRION STRUCTURE

Adenoviruses are nonenveloped icosahedral particles ~90 nm in diameter (Fig. 55.1) with fibers projecting from the vertices of the icosahedron (Fig. 55.2). Most structural studies of adenoviruses have focused on the closely related human adenoviruses types 2 and 5. The particles (virions) have a mass of $\sim 150 \times 10^6$ D³⁵¹ and contain DNA (13% of mass), protein (87% of mass), no membrane or lipid, and trace amounts of carbohydrate because the virion fiber protein is modified by addition of glucosamine.¹⁴⁸ Virions consist of a protein shell (capsid) surrounding a DNA-containing core. Virion polypeptides were initially characterized by disruption of iso-

lated virions with sodium dodecylsulfate and gel electrophoresis.^{209,351} Comparison of electrophoretic results with genomic open reading frames (ORFs) suggests there are 12 virion proteins numbered by convention II-IX, IIIa, IVa, μ , terminal protein, and the p23 viral protease, with no polypeptide I because the moiety originally designated I proved to be a mixture of aggregated molecules (Fig. 55.3, Table 55.2).

The current highest resolution structure of the Ad5 virion is based on 3.6 Å resolution cryo-electron microscopic (cryo-EM)¹⁹⁴ and 3.5 Å resolution x-ray crystallographic²⁷⁴ structures of the entire virion (Fig. 55.1), an ~3 Å resolution x-ray crystal structure of the isolated hexon trimer^{285,286} (Fig. 55.4), and ~1.5 Å resolution structures of the penton base⁴⁰³ (Fig. 55.5A), fiber shaft,³⁵³ and fiber knob³⁵² (Fig. 55.5B). The icosahedral shell is composed primarily of 240 capsomeres of hexon trimers (12 per triangular facet of the icosahedron), 12 pentameric penton capsomeres at each vertex of the icosahedron, and 12 fibers extending from the pentons, each a trimer of the fiber polypeptide. Loops with hypervariable sequence on the external surface of hexons are important for type-specific immunogenicity and neutralization²⁸⁶ (Figs. 55.4C and 55.4D).

Only the bases of the flexible fibers were visualized in the cryoEM structure that depends on methods that average density signals from multiple virions. However, the full lengths of fibers are evident in negatively stained transmission electron micrographs of single virions (Fig. 55.2). Most human adenoviruses encode a single type of fiber. But types 40, 41,¹⁶² and 52¹⁵² encode two fiber proteins, with one or the other bound to each penton base. In contrast, avian adenoviruses also encode two fiber proteins, but one of each binds to each penton base.¹³² Because the fiber knob (Fig. 55.5B) interacts with a cellular receptor protein, the incorporation of two fiber proteins

FIGURE 55.1. Ad5 virion. Color coding (*upper right*) represents distance from the center of the virion in angstroms. (Courtesy of Z. Hong Zhou. Adapted from Liu H, Jin L, Koh SB, et al. might extend the range of cell types to which these viruses bind. The fiber shaft of the HAdVs is composed of repeats of an ~15-residue structural motif,³⁵³ and the length of the shaft varies among types from six repeating units in Ad3 to 21 in Ad2 and Ad5. An unusual “symmetry mismatch” occurs in the

interaction between the fivefold symmetric penton base and the threefold symmetric trimeric fiber. The interaction is mediated by a hydrophobic ring around a central pore on the top surface of the penton base, hydrophobic residues on the bottom of the fiber shaft, and flexible N-terminal tails (aa 10–19) of the fiber monomers (Figs. 55.5B and 55.5C) that insert into three of five available grooves formed by neighboring subunits of the penton base.^{196,403} The N-terminal residues of the fiber monomers (aa 1–9) extend to the bases of penton loops¹⁹⁶ containing RGD sequences that bind to integrins on the target cell plasma

membrane, triggering endocytosis of the virion (see Mechanism of Entry section).

Minor capsid proteins IIIa, VIII, and IX stabilize nonequivalent interactions between hexon trimers, allowing the same hexon trimer to be used in four different chemical environments on the surface of the capsid^{194,274} (Figs. 55.6 and 55.7). Networks of interactions between the minor capsid proteins stabilize two groups of capsomeres and hold them together: a group-of-nine hexon trimers on each triangular facet of the icosahedron,²⁶⁸ and a group-of-six capsomeres at each vertex composed of five hexon trimers with a central penton-base pentamer (Fig. 55.7).

The core of the virion contains seven known viral proteins and the viral genome. Polypeptides VII (174 amino acids), the major core protein with over 800 copies per virion,³⁵¹ and polypeptides V (368 amino acids) and μ (36 amino acids) are basic, arginine-rich proteins^{141,284} that contact the viral DNA^{8,45} and likely condense the viral DNA within the core. Protein VI associates with a cavity on the inner surface of hexon trimers^{261,274,287} (Fig. 55.7B) and with protein V,²¹⁷ tethering the highly ordered capsid to the less ordered DNA-protein core. A basic 115-residue disordered region in the middle of each polypeptide VI is proposed to contribute to an interaction with the core.²⁸⁸ The N-terminus of each penton-base monomer in the pentamer also interacts with the core, and the C-terminus of protein IIIa may as well,¹⁹⁴ consistent with reports that these proteins also interact with protein V^{33,87,300} and that IIIa is responsible for type-specific packaging of viral DNA into virions.²⁰⁶ Protein IVa2 is present in only a few copies at one vertex of the icosahedron,⁵⁵ binds to the packaging sequence at the left end of the genome, and is required for packaging viral DNA into the capsid (see Virion Assembly). The sixth protein in the core is the *terminal protein*, which is covalently

attached to the 5' ends of the viral DNA and therefore present in only two copies per virion. As discussed in Viral DNA Replication below, the terminal protein serves as a primer for DNA replication. The core also contains about 10 molecules of the p23 viral cysteine protease that functions to cleave precursors of several virion proteins during assembly and maturation of the virus particle and in virus disassembly and escape from endosomes during the infection process.³⁶⁷

GENOME STRUCTURE AND ORGANIZATION

Adenovirus genomes are linear dsDNAs ranging in size from 26 to 45 kb.⁷¹ A protein primer of DNA replication called terminal protein is covalently bound to the 5' phosphate of each strand (see Viral DNA Replication). Homologous genes shared by all adenoviruses encode the three viral proteins required for viral DNA replication, the terminal protein, viral DNA polymerase, and viral single-stranded DNA (ssDNA) binding protein, and major structural components of the virion described (see Virion Structure), except that genes encoding the core protein V are found only in the mastadenoviruses isolated from mammals.⁷¹ These common genes are encoded in the central portion of the genome. Additional genes specific to adenoviruses from different vertebrates are encoded primarily at the termini of the genome. Also, the genomes of all adenoviruses have inverted terminal repeat sequences ranging in size from 36 to over 200 bp.⁷¹ As discussed in Viral DNA Replication below, the inverted repeats function as DNA replication origins at each end of the viral genome and enable single strands of viral DNA displaced during asymmetric strand synthesis to circularize by base-pairing of their terminal sequences. The resulting

base-paired “panhandles” in the otherwise ssDNA molecules function as origins for replication of displaced single strands.

Most human adenovirus genomes encode homologous genes represented by the extensively studied, closely related human species C adenoviruses types 2 and 5 (Fig. 55.8). HAd2 DNA was the first adenovirus genome to be completely sequenced,²⁷⁹ and it includes a total of 35,937 base pairs (bp). This chapter will concentrate on the human adenoviruses, all having the same general genome organization.

The human adenovirus genomes include several repeats of a *cis*-acting packaging sequence between the left terminal

repeat and the first protein-coding region (E1A).¹²⁹ This packaging sequence must be located within several hundred bp of an end of the chromosome to direct the proper packaging of viral DNA into infectious virions.¹²⁹

The human adenovirus genomes contain five early transcription units (E1A, E1B, E2, E3, and E4), four intermediate transcription units transcribed at the onset of viral DNA replication (IX, IVa2, L4 intermediate, and E2 late), and one late transcription unit (major late) that is processed to generate five families of late mRNAs (L1–L5), all of which are transcribed by RNA polymerase II (Fig. 55.8). As discussed in

FIGURE 55.5. Structures of Ad2 penton base and fiber. **A:** Space filling model of a penton base. Each of the five penton base subunits is shown in a separate color. **B:** Model of fiber shaft and knob. Each of the three fiber subunits is shown in a separate color. **C:** View of the fiber shaft from the bottom with three fiber N-terminal tails that fit into three of five grooves between the subunits at the top of the penton base. FIGURE 55.6. Four different chemical environments of hexon trimers and locations of minor cement proteins. Models of one of the twenty facets of an Ad5 icosahedron viewed from outside (*exterior*) and inside (*interior*) the virion. Penton bases with the base of a fiber trimer are at the three corners of the triangular facet. Hexon trimers are in four distinct chemical environments, each shown in a different color shade: (H1) two hexon trimers neighboring each penton base; (H2) two hexon trimers on the edges of each facet between the penton base-associated hexon trimmers; (H3) three hexon trimers at the center of each facet; and (H4) three hexon trimers between the central hexon trimers and the penton-associated hexon trimers. These nonequivalent interactions are stabilized by protein IX (purple) between hexon trimers, visible from the exterior surface, and proteins IIIa (red) and VIII (blue) on the inner surface. (Courtesy of Z. Hong Zhou. Adapted from Liu H, Jin L, Koh SB, et al. Atomic structure of human adenovirus by cryo-EM reveals interactions among protein networks. *Science* 2010;329:1038–1043.)

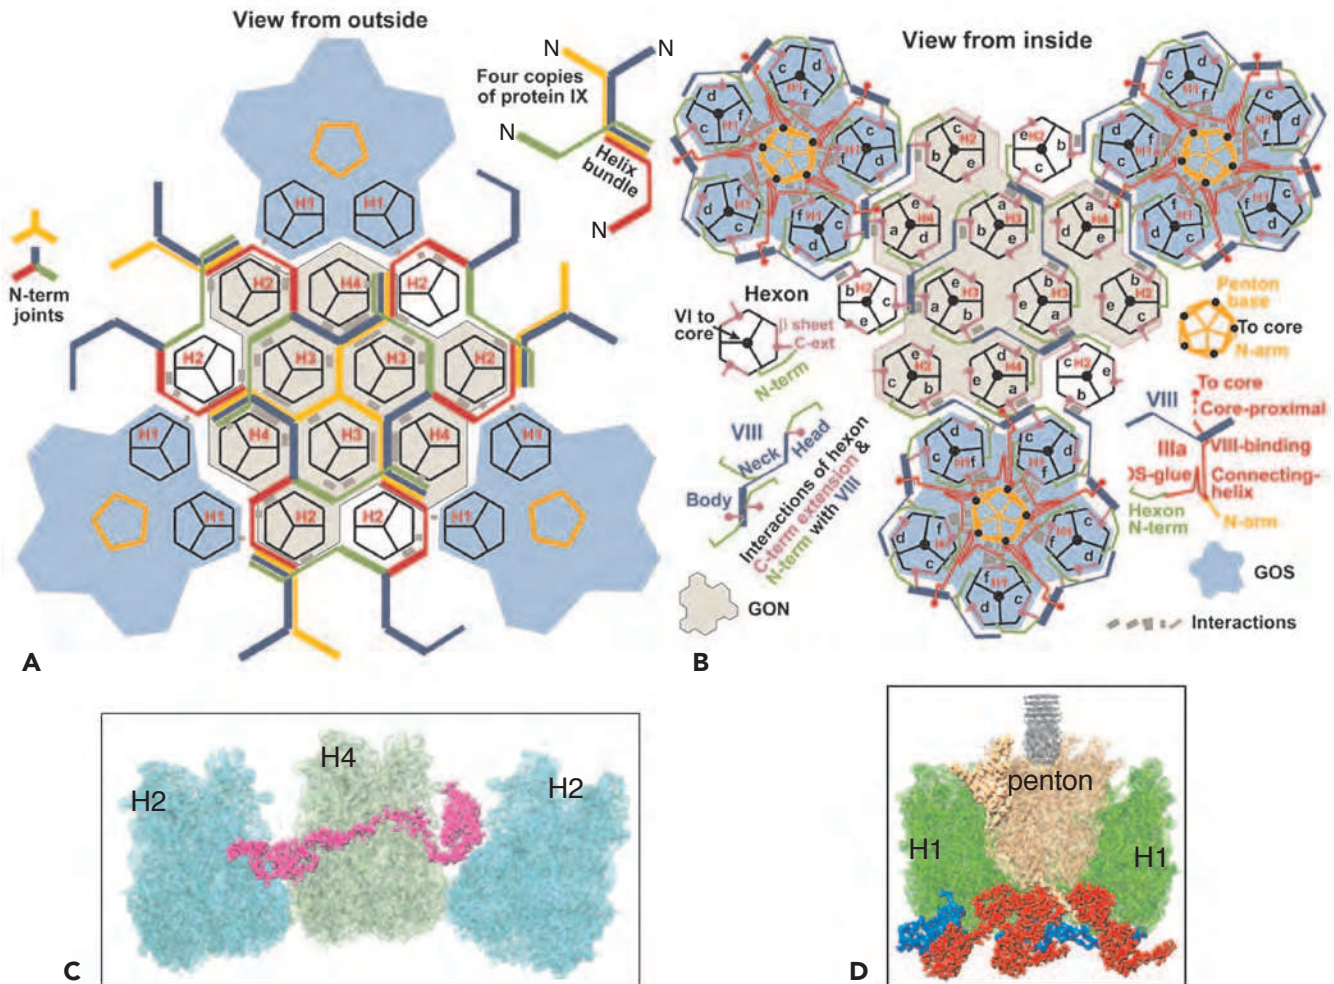

FIGURE 55.7. Diagram of the interactions of minor proteins IIIa, VIII, and IX that stabilize nonequivalent hexon trimer interactions. **A:** Hexon trimers are labeled H1 to H4 as described in Figure 55.6. The diagram at the upper right represents four different conformations of protein IX shown in different colors. N indicates their amino termini. These link hexon trimers in a group of nine (gray), and link groups of nine from neighboring facets. Groups-of-nine hexon trimers are released when virions are disrupted under mild conditions.²⁶⁸ **B:** Letters a through f indicate hexon monomers with distinct conformations of their extended N- and C-termini. As diagrammed at the lower left, three hexon C-termini and four hexon N-termini interact with one protein VIII. At each vertex of the icosahedron, five copies of protein IIIa link five hexon trimers to the central penton base, forming a group-of-six capsomeres (GOS, shaded in blue). Protein VIII links groups-of-nine hexon trimers (GON) to groups-of-nine hexon trimers in neighboring facets and groups-of-nine hexon trimers to groups-of-six capsomeres at the vertices. Protein VI binds in a central cavity on the inner surface of hexon trimers, represented as a black circle. **C:** Side view of protein IX (purple) inlaid into the canyons between hexon trimers. **D:** Side view of proteins IIIa (red) interacting with penton base and H1 hexons and protein VIII (blue) interacting with H1 hexons on the inner surface of the capsid shell. (Courtesy of Z. Hong Zhou. Adapted from Liu H, Jin L, Koh SB, et al. Atomic structure of human adenovirus by cryo-EM reveals interactions among protein networks. *Science* 2010;329:1038–1043.)

the Late Transcription section, the major late promoter is also transcribed at a low level early during infection, generating one of the L1 family mRNAs encoding the p52/55 kD protein (a 48-kD polypeptide that runs as an apparent doublet of 52 and 55 kD on SDS polyacrylamide gels because of variation in the degree of phosphorylation). Also, after the onset of viral DNA replication, the E2 transcription unit is transcribed from an alternative promoter called the E2 late promoter as well as the early E2 promoter active before and after the onset of viral DNA replication. The chromosome also carries one or two (depending on the type) virus-associated (VA) genes transcribed by

RNA polymerase III. By convention, the map is drawn with the E1A gene at the left end. Both strands of the viral DNA are transcribed with the rightward reading strand as the template for the E1A, E1B, IX, major late, VA RNA, and E3 transcription units, and the leftward reading strand as the template for the E4, E2, and IVa2 units.

Except for the IVa2 and pIX transcription units, each of the adenovirus genes transcribed by RNA polymerase II gives rise to multiple mRNAs that are differentiated by alternative splicing, and in the case of the major late, E2, and E3 transcription units by the use of alternative poly(A) sites as well. The L4

FIGURE 55.8. Genomes of adenoviruses type 2 and type 5. The genome of 35,937 base pairs (type 2) is divided into 100 map units. Early mRNAs are diagrammed with their exons represented by *thin lines*, late mRNAs with *heavy lines*, and intermediate RNAs (IX, IVa2, L4 intermediate, and E2A late) by *lines of intermediate thickness*. Arrowheads represent polyadenylated 3' ends. Most late mRNAs originate at the major late promoter (MLP) at 16.8 map units and contain the tripartite leader whose exons are labeled 1, 2, and 3. E2B mRNAs encoding the adenovirus DNA polymerase (AdPol, 140K) and terminal protein precursor (pTP, 87K) are also expressed from the E2 late promoter and contain the same noncoding 5' exon as the E2A late mRNAs. The L4 intermediate mRNAs encoding proteins L4 22K and L4 33K (from the spliced mRNA) are inferred from the recent discovery of a promoter at ~72 map units and expression of these proteins at intermediate times postinfection.²²⁶ Proteins translated from the mRNAs transcribed to the right and left are named at the top and bottom, respectively. Penton represents the penton base, which is also designated virion protein III. Hexon is also designated virion protein II, and fiber, virion protein IV. pVI, pVII, and pVIII refer to precursor polypeptides that are cleaved during virion maturation. 52/55K represents a single protein that migrates as a doublet on SDS-polyacrylamide gels because of heterogeneous phosphorylation.

intermediate mRNAs shown in Figure 55.8 encoding proteins L4 22K and L4 33K (the spliced mRNA) are inferred from the recent discovery of a promoter at ~72 map units and expression of these proteins at intermediate times postinfection.²²⁶ As mentioned earlier, the analysis of adenovirus mRNA structure led to the discovery of RNA splicing^{24,53} (Fig. 55.9).

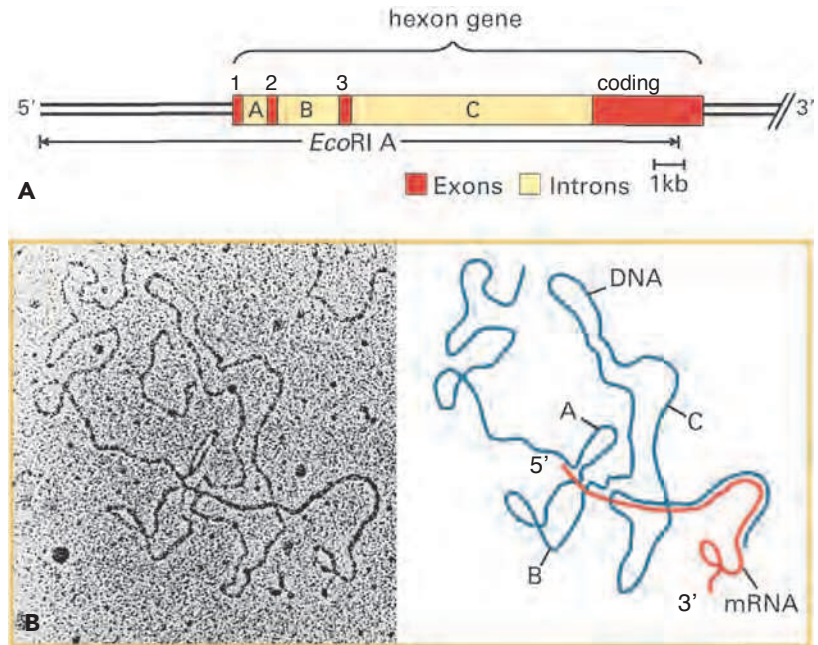

Some of the protein products generated from the same transcription unit share amino acid sequence, such as the two major polypeptides encoded by the E1A region (Fig. 55.10) and the 22K and 33K proteins of the L4 region (Fig. 55.11). Others have no sequence in common, such as the two major E1B-coded proteins (Fig. 55.10) and the 100K, 22K, and pVIII proteins encoded in the L4 region (Fig. 55.11). No consistent terminology has been adopted for naming viral proteins: the early E1A proteins are named large and small E1A proteins and are often referred to by the sedimentation coefficient of the mRNAs that encode them (13S and 12S); E1B and E3 proteins are designated by their apparent molecular mass estimated from SDS gel electrophoresis; E2 proteins are named for

their functions; E4 proteins are named for ORFs; and the proteins encoded by the major late transcription unit are named for the virion proteins discussed above in Virion Structure and the molecular mass for nonvirion proteins. The various historical names of viral polypeptides are used in this chapter, generally preceded by the name of the transcription unit or family of late mRNAs that encodes them (e.g., E4orf6, L4-100K).

Many of the individual adenovirus transcription units encode a series of polypeptides with related functions. As will be discussed, the E1A unit encodes two principle proteins that activate transcription and induce the host cell to enter the S phase of the cell cycle; E1B encodes two proteins that block apoptosis; E2 encodes three proteins that function directly in DNA replication; E3 encodes products that modulate the response of the host to infection; and the late family of mRNAs is concerned with the production and assembly of capsid components. Only the E4 unit encodes an apparently disparate set of functions. E4 products mediate transcriptional, RNA splicing, and translational regulation; mRNA nuclear export;

FIGURE 55.9. Discovery of spliced Ad2 hexon mRNA by electron microscopy of an RNA-DNA hybrid.

A: Diagram of the Ad2 EcoRI A fragment and the hexon gene with exons 1, 2, and 3 comprising the 5' tripartite untranslated leader region and the 3' coding exon shown in red, and introns labeled A, B, and C. **B:** Electron micrograph of a hybrid between hexon mRNA and the EcoRI A coding strand visualized by formamide spreading. In this method, RNA-DNA hybrid appear as a smooth filament whereas single-stranded DNA and RNA appear slightly thinner and less smooth.⁷⁰ A diagram of this RNA-DNA hybrid is shown at the right with hexon mRNA in red and single-stranded DNA of the hybridized EcoRI A fragment in blue. Regions where the red RNA parallels the blue DNA represent base-paired regions of the RNA-DNA hybrid. (**B, left**, from Berget SM, Moore C, Sharp PA. Spliced segments at the 5' terminus of adenovirus 2 late mRNA. *Proc Natl Acad Sci U S A* 1977;74:3171–3175, with permission.)

and modulate DNA replication and apoptosis. The grouping might be driven in part by the advantage of using a single transcriptional control element to regulate the expression of multiple polypeptides that are needed simultaneously to execute a function such as DNA replication. As for bacteriophage, the grouping of coding regions for products that interact physically or functionally may have been selected during virus evolution so that recombination between different viral genomes in co-infected cells did not separate genes for interacting proteins.

STAGES OF REPLICATION

The replication cycle is divided by convention into two phases that are separated by the onset of viral DNA replication. Early events commence as soon as the infecting virus interacts with the host cell. These include adsorption, penetration, movement of partially uncoated virus particles to a nuclear pore complex (NPC), transport of viral DNA through the NPC into the nucleus, and expression of an early set of genes. Early viral gene products mediate further viral gene expression and viral DNA

replication, induce cell cycle progression (presumably to activate host cell genes for nucleotide and protein synthesis), block apoptosis, and antagonize a variety of host antiviral measures (see Chapter 56, Adenoviruses by W.S.M. Wold and M. Ison). In HeLa cells infected at a multiplicity of 10 plaque-forming units per cell, the early phase lasts ~ 6 hours, after which viral DNA replication is first detected. Concomitant with the onset of viral DNA replication, the late phase of the cycle begins with expression of late viral genes and assembly of progeny virions. The infectious cycle is completed after 24 to 36 hours in HeLa cells. At the end of the cycle, about 10^5 progeny virus particles per cell have been produced, along with the synthesis of a substantial excess of virion proteins and DNA that are not assembled into virions.¹¹³ Cells infected at high multiplicity seldom divide; hence, at the completion of the replication cycle, the DNA and protein content of the infected cell has increased by a factor of about two.

Studies of the human adenovirus replication cycle have focused primarily on the closely related HAdV-2 and HAdV-5 (Ad2, Ad5) viruses. These closely related types have been favored because they are easily grown in the laboratory, and

FIGURE 55.10. Ad2 and Ad5 major E1A and E1B mRNAs and proteins expressed during the early phase of infection and in transformed cells. The large and small E1A proteins are translated from spliced mRNAs with single introns having alternative 5' splice sites and the same 3' splice site (12S and 13S E1A mRNAs). Translation starts at the first AUG of both mRNAs, and the second exon of both mRNAs is translated in the same open reading frame. As a consequence, the large E1A protein (289 aa residues) contains 46 amino acids near the middle of the protein that are absent from the small E1A protein.²⁶³ Two E1B proteins of 21K (often called 19K because of its apparent molecular weight on SDS-polyacrylamide gels) and 55K are translated from the first and second AUG in alternative reading frames of the large, 22S E1B mRNA. The 21K protein is also expressed from the first AUG of the smaller 13S E1B mRNA.³⁰

FIGURE 55.11. Ad5 mRNAs and proteins from the L4 region. The three alternative reading frames of the genome sequence are shown in blue, red, and yellow. Dashed lines at the left represent splicing to the third exon of the tripartite leader.

an extensive collection of mutant viruses have been developed. When other human types have been studied, their growth strategies usually have proved similar to the paradigm established for these prototypes. Most studies of adenovirus growth have been performed by infection of HeLa or KB cells at fairly high

multiplicities of infection (more than 10 plaque-forming units per cell). High multiplicities of infection have been used so that all cells in the culture are synchronously infected, allowing the ordered series of biochemical events during the infectious cycle to be observed in a time-wise fashion. HeLa and KB cells have been favored as hosts because they are easily propagated in large quantities, and because Ad2 and Ad5 grow in them rapidly and to high yield. These tumor cells support more rapid viral growth than human diploid fibroblasts, in which the replication cycle is prolonged to about twice as long due to extension of the early phase of infection.¹⁰⁷

Mechanism of Attachment

Adenovirus uses distinct cellular receptors for attachment and internalization (Fig. 55.12). Initial attachment of HAdVs in species A, C, D, E, and F (but not species B) is mediated by high-affinity binding of the fiber knob domain⁷⁵ to the host-cell transmembrane CAR protein (coxsackie B, adenovirus receptor).^{23,281,339} The CAR protein (345 residues in human) is a component of epithelial cell tight junctions with extracellular domains in the immunoglobulin (Ig) superfamily.⁵⁸ It is

FIGURE 55.12. HAdV Attachment, internalization, intracellular transport and uncoating. (1) The fiber knob binds to the primary cellular receptor, CAR (HAdV species A, C, D, E, F) or CD46 (HAdV species B). (2) The RGD region of the penton monomers (Fig. 55.4A) bind α_v integrins, stimulating endocytosis in clathrin coated vesicles for species C. (3) Fibers begin to dissociate from pentons at the plasma membrane and completely dissociate in early endosomes. (4) The vertices of the particle composed of penton base and peripentoneal hexon trimers dissociate in endosomes, probably as a result of acidification, and the internal capsid proteins IIIa, VI, and VIII are released. Protein VI lyses the endosome, releasing the partially uncoated particle into the cytosol (5) where it is transported on microtubules by dynein motor proteins to the microtubule organizing center, and then associates with the cytoplasmic filament nucleoporin NUP214/CAN (6). The viral DNA bound by protein VII is then imported through the nuclear pore complex by the abundant importins Transportin and Imp7. (Adapted from Nemerow GR, Pache L, Reddy V, Stewart PL. Insights into adenovirus host cell interactions from structural studies. *Virology* 2009;384:380–388; and Greber UF. Signalling in viral entry. *Cell Mol Life Sci* 2002;59:608–626.)

abundantly expressed in heart, pancreas, the central and peripheral nervous systems, prostate, testis, lung, liver, and intestine, but little or no CAR is expressed on hematopoietic cells or adult muscle.²²⁰ Infection does not require the CAR cytoplasmic or transmembrane domains,³⁶³ implying that CAR function in infection is primarily as an anchor for high-affinity binding. The finding that most CAR is localized below the apical surface of polarized epithelial cells comprising the respiratory epithelium at tight junctions on the basolateral surface raises the question of how species C respiratory HAdVs like types 2 and 5 initially infect such tissues from the luminal side. It has been suggested that infections may initiate in specialized nonpolar cells that express CAR on their apical surface, or that lesions of the epithelium are required to expose basolateral surfaces of epithelial cells during the initial phase of infection.²²⁰

The x-ray crystal structure of a complex between the HAdV-12 fiber knob and the extracellular N-terminal Ig-like domain (D1) of CAR showed that three CAR molecules bind to the three interfaces between fiber knob monomers²⁶ through the same surface used by CAR for homotypic interactions.⁹⁹ The avidity generated from the three independent interactions generates high-affinity binding with a $K_D \approx 1$ nM.²⁰⁰ Free fiber proteins produced during the late phase of infection in excess over fiber proteins incorporated into virions are released with progeny virions from the basolateral surfaces of infected airway epithelial cells and interfere with CAR oligomerization at tight junctions. This probably promotes release of progeny virions to the airway lumen.³⁵⁹ In this way, the fiber–CAR interaction serves two functions: initial attachment of virions to host cells during infection, and dissemination of progeny virions to new host cells and host organisms.

In contrast to other HAdV species, fiber knobs of HAdVs in the B species and species D HAdV-37 bind CD46, a regulator of the complement cascade present on the plasma membrane of most cell types including hematopoietic cells.^{102,295,301,382} As in the case of CAR binding, three CD46 extracellular domains are bound by the three fiber monomer interfaces in the fiber knob.²⁶⁴

As mentioned earlier, HAd-40 and -41 incorporate one of two different fibers at each vertex of the virion. The longer of these binds to CAR. The receptor for the second, shorter fiber protein of HAdV-40 and -41 is not known, but it is postulated to contribute to the tropism of these viruses for intestinal epithelium and hence the enteritis with which they are associated.⁶⁰ The stability of HAdV-40 and -41 at low pH no doubt also contributes to this tropism.⁸⁹

The fiber knob of HAdV species D type 37 and probably other species D types can bind three molecules of sialic acid near its top³⁹ as opposed to the interaction of CAR and CD46 with the lateral surface of the fiber knob. Consequently, this terminal saccharide present on many glycoproteins may also function as an initial attachment site for HAdV species D types. Infection by HAdVs elicits a potent, long-term humoral immune response. While most neutralizing antibodies bind to the major virion protein hexon and are primarily responsible for the classification of HAdVs into serotypes,^{104,266,278,323,340} neutralizing antibodies to fiber are also generated⁹⁰ and neutralize synergistically with antibodies to penton base, which interacts with the secondary HAdV receptor.¹⁰³

In addition to these well-studied host receptors, experiments with HAdV-5–based gene delivery vectors led to the

discovery that most vectors infect hepatocytes following intravenous administration. This was found to result from binding of coagulation factor X through its negatively charged Gla-domain to the central depression of the Ad5 hexon and subsequent uptake into hepatocytes through an interaction with heparan sulfate proteoglycans.³⁵⁷ A review of other potential receptors for human adenoviruses in specific tissues is presented in.¹⁴

Mechanism of Entry, Intracellular Trafficking, and Uncoating

Following high-affinity binding of the HAdV-5 fiber knob to CAR, the RGD loop domains of penton base subunits (Fig. 55.5) associate with $\alpha v\beta 3$ and $\alpha v\beta 5$ integrins on the host-cell surface with 50-fold lower affinity than the interaction of fiber with CAR^{234,235,373} (Fig. 55.12). Integrins are abundant heterodimeric transmembrane proteins involved in cell adhesion to the extracellular matrix and neighboring cells via RGD peptide motifs in the bound, extracellular protein and are exploited by many viruses for cell entry.³¹⁶ At saturation, ~4 integrins are bound to the pentameric penton base.⁵² Neutralizing antibodies that bind loops on the outer surface of penton are generated that block association with integrins.¹³⁷ However, a monoclonal antibody directed against the RGD loop cannot neutralize the virus, whereas Fab fragments from the same antibody can.³¹⁵ This is presumably because steric hindrance due to the central fiber and the short distance (~60 Å) between the RGD loops prevents binding of the intact antibody to all five penton base subunits.

Interaction of the penton base with integrins is presumably facilitated by their high local concentration resulting from high-affinity binding of the fiber knob to transmembrane CAR. Binding of the penton base to integrins requires the flexibility of the fiber shaft.³⁸¹ Clustering of integrins through the binding of several integrins to the subunits of one pentameric penton base triggers integrin transmembrane signaling, leading to activation of phosphoinositide-3-OH kinase (PI3K), p130CAS, and Rho family GTPases.¹⁸⁶ This results in the localized actin polymerization required for endocytosis of the virion via clathrin-coated pits in the classic receptor-mediated endocytosis that involves clathrin adapters and the large GTPase dynamin²²⁰ (Fig. 55.12). Dynamin multimerizes into a spiral-shaped structure that promotes the membrane fusion required for separating an endosome from the plasma membrane.^{105,201,362}

In contrast to the other HAdV species, species B HAdVs, with fiber knobs that bind CD46 as the primary receptor, enter cells through a subsequent penton base interaction with αv integrins that stimulates an alternative, clathrin-independent mechanism of endocytosis called macropinocytosis.^{6,154} Macropinocytosis generates large vesicles near the plasma membrane and requires activation of the PAK1 protein kinase, protein kinase C (PKC), the small GTPase Rac1, Na^+/H^+ exchangers, and the C-terminal binding protein 1 (CtBP1). CtBP1 (C-terminal binding protein) is so named because it binds to the C-terminal conserved region 4 of HAdV E1A proteins.⁵¹ Remarkably, CtBP1 and 2 also function in the nucleus to regulate transcriptional activation by E1A (see Regulation by E1A). Species C HAdVs also stimulate macropinocytosis, but do not use this process as a primary route of infection.²¹⁹ However, this phenomenon probably accounts for the observation that infection of cells with untreated or inactivated HAdV-2 or -5 can stimulate uptake of macromolecules from the medium.^{59,95}

Uncoating of the virion begins at the cell surface. The interaction of penton base with integrins at the cell surface and during endocytosis leads to detachment of fibers, so that a fiberless virion is endocytosed.²³² Structural studies revealed substantial conformational flexibility in the central region of the penton base pentamer such that an ~ 15 Å diameter pore in the cryoEM structure of wild-type HAdV-5¹⁹⁶ becomes an ~ 28 Å pore in the x-ray crystal structure of the isolated penton base⁴⁰³ and can expand to a diameter of ~ 50 Å in the crystal structure of an HAdV-5 engineered with a short fiber derived from HAdV-35 to facilitate crystallization.²⁷⁴ Such an expansion of the penton base central pore may facilitate release of the fiber. Studies of virion disassembly using fluorescently labeled virions and fluorescence resonance energy transfer (FRET), fluorescence anisotropy measurements of the segmental motions of fluorophores, and fluorescence lifetime imaging microscopy using a pH-sensitive probe indicated that the half-time for detachment of the fiber is 3 minutes following adsorption at 4° followed by warming to 37°.²¹⁴

Following endocytosis of clathrin-coated vesicles containing HAdV-2, the vesicles mature into endosomes, and subviral particles lacking fibers escape from endosomes into the cytosol ~ 15 minutes after binding to the cell surface.¹¹⁰ Release from endosomes may require further signaling from α_v integrins following endocytosis since release is blocked by inhibitors of protein kinase C, which prevent transport of virion containing vesicles through the actin cortex under the plasma membrane into the cytosol.^{109,232} Release of penton base, peripentoneal hexon trimers and the internal capsid proteins IIIa, VI, and VIII occurs in the endosome, thought to be triggered in part by acidification during endosomal maturation¹¹² (Fig. 55.12). Exposure to a reducing environment in the maturing endosome also results in re-activation of the virion-associated viral protease, which functions during virion assembly (see Virion Assembly), and cleavage of protein VI. This is required for final disassembly of subviral particles at nuclear pore complexes and DNA import into the nucleus.¹¹¹ Lysis of the endosome and release of partially uncoated virions into the cytosol is mediated by an amphipathic helical, membrane lytic domain of protein VI³⁷⁵ that appears to be sequestered in the intact virion in cavities on the inner surface of hexon trimers.²⁷⁴ Thus, the virion, which is very stable outside the cell, is dismantled by an ordered elimination of structural proteins on entry to the cell so that it can deliver its DNA to the nucleus.

For HAdV species A, B, C, and D, release of penton base and protein VI and lysis of endosomes are blocked by α -defensins, antimicrobial cysteine-rich peptides released from host neutrophils.^{181,239,305} CryoEM and other studies indicate that thousands of defensin molecules bind to HAdV species A, B, C, and D (but not E or F) virions. Defensins bound at the interface between fiber and penton base are particularly important for inhibiting infection by preventing the loss of the vertex region and therefore preventing escape of protein VI and endosome lysis.³⁰⁶ As a consequence, virion-containing endosomes mature into late endosomes and fuse with lysosomes where virion proteins and DNA are degraded.³⁰⁶ Anti-hexon neutralizing antibodies cross-link hexons and also may prevent the release of peripentoneal hexons as well as the subsequent release of protein VI and endosome lysis so that virions are delivered to lysosomes and degraded.

In the absence of these host defenses, endosomal lysis occurs. The subviral particles released into the cytosol are

transported to the nucleus on microtubules^{66,183,207} (Fig. 55.12). Fluorescently labeled virion particles in live cell imaging are observed to switch rapidly between minus-ended microtubule motility toward the juxtanuclear microtubule organizing center (MTOC) and plus-ended motility away from the nucleus. But transient activation of protein kinase A (PKA) by integrin signaling and activation of the p38 MAP kinase and its target MAPKAP kinase 2 (MK2) by an unknown mechanism increase the frequency and velocity of minus-end directed movement of subviral particles by the dynein motor protein complex³²⁴ until they reach the MTOC.¹⁸ One neutralizing monoclonal antibody to hexon does not interfere with endosome lysis, but rather blocks infection by inhibiting the association of virions with microtubules, suggesting that it is hexon that binds to microtubule motors.³⁰⁴

From the juxtanuclear MTOC, subviral particles associate with nuclear pore complexes (NPCs)¹¹⁰ via an interaction between hexon trimers and the FG-repeat-containing domain of NPC cytoplasmic filament protein CAN/Nup214.³⁴⁴ Surprisingly, the activity of exportin 1 (CRM1), a nuclear export factor, is required for this association with the cytoplasmic side of NPCs since association of subviral particles with NPCs is blocked by leptomycin B and ratjadone A, highly specific inhibitors of exportin 1, and by small interfering RNA (siRNA) to exportin 1 mRNA.³²¹ But how exportin 1 functions in this process is unclear.

The diameter of subviral particles bound to the NPC (~ 90 nm) is too large to pass through diffusional channels in the pore, ~ 5 to 9 nm.⁴ Viral uncoating occurs at the nuclear pore as shown by exposure of core polypeptide VII and hexon epitopes that are hidden in intact virions.¹¹⁰ Association of intact subviral particles with NPCs occurs by ~ 60 minutes postinfection, and particle disassembly assayed by epitope exposure occurs by ~ 120 minutes.³⁴⁴ FRET experiments with fluorescently labeled virions indicate that the half-time for disassembly of the icosahedral capsid, probably coincident with unpackaging at the NPC, is 60 minutes.²¹⁴ Blocking NPC binding by microinjection of wheat germ agglutinin or specific antibodies that bind to central domains of the NPC blocked exposure of the epitopes, indicating that an interaction with the NPC is required to trigger final capsid disassembly.¹¹⁰ This mechanism assures that viral DNA is released only at the NPC in preparation for transport into the nucleus.

Viral DNA bound by the major basic core protein VII^{110,310,358,386} enters the nucleus by ~ 120 minutes postinfection, while most hexon and protein IX remain associated with NPCs, indicating that the viral DNA–protein VII complex separates from the partially dissociated capsid during the nuclear import process.¹¹⁰ Protein VII and the viral DNA to which it is bound are imported into the nucleus by a Ran-dependent mechanism involving protein VII binding by the abundant importin Transportin.^{135,379} In addition, free histone H1, which is known to be in rapid dynamic equilibrium with chromatin-bound H1,^{184,223} binds to a cluster of 16 acidic residues on one of the hexon surface loops conserved among type C HAdVs.³⁴⁴ Subsequent import of a small fraction of the hexon complexed to histone H1 by an Importin 7–importin β heterodimer is proposed to contribute to the nuclear import of the viral DNA–protein VII complex.³⁴⁴ Experiments with HAdV-2 containing a green fluorescent protein–protein V fusion in its core indicate that the core protein V remains on the cytoplasmic side of the

nuclear pore and does not enter the nucleus with the protein VII–viral DNA complex.²⁷⁰ Protein VII remains associated with viral DNA after its import into the nucleus until it is dissociated by transcription of the viral genome.^{47,358,386}

The process of HAdV infection activates several components of the innate immune response that recognize pathogen-associated molecular patterns (PAMPs). Binding of purified recombinant HAdV-5 fiber knob to the CAR receptor of human A549 cells derived from alveolar type II epithelial cells caused a sharp peak in activity of MAP kinases ERK1/2 and JNK 5 to 20 minutes after addition to cells, and NF- κ B translocation to nuclei by 4 hours.³²⁷ Although the mechanism of signaling between fiber knob bound CAR and the MAP kinase and NF- κ B activation pathways remains unclear, this was associated with expression of proinflammatory chemokines interleukin-8, CXCL-1 (GRO- α), CXCL-3 (GRO- γ), CCL5 (RANTES), and CXCL-10 (interferon-inducible protein 10). No activation was observed with purified penton base or hexon.³²⁷ Toll-like receptor 9 (TLR9) is activated by viral DNA released into endosomes in plasmacytoid dendritic cells, resulting in secretion of type 1 interferon α .^{21,42,146,399} In macrophage, following endosomal lysis by protein VI, the cytosolic NLRP3 inflammasome²⁶⁵ is activated by released cytosolic viral DNA. This triggers activation of caspase 1, which processes pro interleukins 1 β and 18, leading to their secretion.²³⁰ In mouse models of intravenous administration of defective HAdV vectors, infection of splenic macrophage led to secretion of the potent interleukin 1 α .⁷⁶ These and potentially other innate proinflammatory immune responses likely contributed to the well-publicized fatal systemic inflammatory syndrome in an ornithine transcarbamylase (OTC)–deficient patient following infusion into a hepatic artery of 4×10^{13} particles of an HAdV-5 gene therapy vector with a substitution of an OTC expression cassette for the viral E1A and E1B regions and deletion of E4.²⁷²

The robust humoral adaptive immune response elicited by HAdV infections in immunocompetent patients results in production of neutralizing antibodies primarily to hexon, but also to fiber and penton base as discussed previously. In addition, a cellular adaptive immune response is induced. Both cytotoxic CD8⁺ T-cell^{179,180,328,329} and memory CD4⁺ T-cell^{179,245,328} responses occur to epitopes in hexon that are highly conserved between different HAdV species. Consequently, it has been suggested that adoptive transfer of adenovirus-specific T cells from healthy adults may be useful in preventing or treating HAdV infections of multiple different types in immunocompromised patients.¹⁷⁹

Transcription

As mentioned previously, during the infection process adenovirus DNA is transported into nuclei bound by the most abundant virion core protein, the 20-kD, highly basic protein VII.^{110,310,358,386} Protein VII serves the crucial role of suppressing activation of the cellular dsDNA break response (DSBR) when the viral DNA associated with protein VII first enters the nucleus.¹⁵⁸ In the absence of such protection, the cellular MRE11–RAD50–NBS1 complex is activated by the termini of the viral DNA and degrades the ends of the genome, inhibiting viral DNA replication.¹⁵⁸

Release of core protein VII to facilitate transcription of the infecting viral genome is stimulated by its interaction with several abundant acidic nuclear proteins, including template

activating factor I.¹²⁰ The normal function of this protein is to remove protamine from sperm chromatin following oocyte fertilization,²¹⁶ a similar process in that small basic proteins are removed from DNA. Chromatin immunoprecipitation assays¹⁶⁸ indicate that cellular histones replace much of protein VII early in infection by a mechanism that requires viral transcription,⁴⁷ generating viral genomes bound by both protein VII and acetylated nucleosomes. The DNA of an HAdV-5–based gene therapy vector was also shown to be assembled into physiologically spaced nucleosomes containing histone H3.3, the isotype associated with transcribed cellular genes, dependent on the activity of the histone chaperone HIRA.²⁸² Further convincing evidence for the association of host histones with adenoviral DNA early during infection came from immunofluorescence microscopy showing co-localization of phosphorylated histone H2AX with infecting viral genomes of an E4orf3-minus/E4orf6-minus double mutant that induces a dsDNA break response (see E4).¹⁵⁸

Although early and late are convenient terms for description of events that occur during the replication cycle, the functional distinction between early and late events is often blurred. Early genes continue to be expressed at late times after infection, and the promoter controlling expression of the major late transcription unit directs a low level of transcription early after infection. Also, the viral genes encoding proteins IVa2, IX,²⁸ L4-22K and L4-33K²²⁶ begin to be expressed at an intermediate time, thus forming a delayed-early category.

Regulation of Viral and Host-Cell Transcription by E1A Proteins

There are three main goals of early adenovirus gene expression. The first is to induce the host cell to enter the S phase of the cell cycle, providing an optimal environment for viral replication. E1A and E4 gene products play roles in this process. The second is to set up viral systems that protect the infected cell from various antiviral defenses of the host organism. The E1A, E1B, E3, and VA RNA genes contribute to these defenses, which are also discussed. The third is to synthesize viral gene products needed for viral DNA replication. All three of these goals depend on transcriptional activation of the viral genome and the induction of S-phase in noncycling cells in order to provide the precursor dNTPs required for viral DNA synthesis, NTPs and RNA processing proteins required for viral mRNA synthesis, and to activate pathways required for protein synthesis.

The E1A region is the first region to be transcribed following infection²³⁷ due to strong enhancer activity of the ~500 bp upstream of the E1A promoter.¹³⁰ Two major E1A mRNAs and encoded proteins are expressed early after infection from alternatively spliced mRNAs that use one of two 5′-splice sites separated by 138 bp and the same 3′ splice site²⁶³ (Fig. 55.10). Large E1A protein auto activates transcription of the E1A region about fivefold and stimulates transcription from the E1B, E2 early, E3, and E4 start sites more than 10- (E1B) to about 100-fold (E2early, E3, and E4).^{224,225,378} Activation requires a stable, highly specific interaction of the unique region of the large E1A protein, conserved region 3 (CR3), with the MED23 subunit of the human Mediator of transcription complex.^{35,314} Activation domain interactions with the Mediator MED23 subunit both increase the assembly of preinitiation complexes on promoters and stimulate transcription elongation.^{40,360} An interaction between CR3 and the major cellular nuclear acetyl transferase

FIGURE 55.13. Protein–protein interaction domains of the large E1A protein. Extensively conserved amino acid sequences in the primate adenoviruses are designated CR1, 2, 3, and 4, although the N-terminal region is also extensively conserved.²⁷³ The two regions of both large and small E1A that interact with the closely related nuclear lysine amino transferases p300 and CBP are shown in yellow. The two regions that associate with the pocket domain of RB-family proteins are shown in blue. The N-terminal C4-Zn-finger region in CR3 unique to the large E1A protein that binds the MED23 subunit of the mediator of transcription complex and the C-terminal region of CR3 proposed to interact with the DNA-binding domains of host-cell transcription factors that bind the early viral promoters¹⁹³ are diagrammed in green. CR4 is shown in red. It includes a C-terminal nuclear localization signal and a PXDLS sequence bound by CtBP 1 and 2 N-terminal to the nuclear localization signal.^{51,205}

p300 also contributes to early gene activation by large E1A.^{259a} In addition, a glutamic acid-proline repeat, (EP)₆, immediately C-terminal to CR3 in Ad2 and Ad5, is essential for large E1A activation of the early adenovirus promoters.³²⁰ Finally, the CR3 region of Ad5 also interacts with the lysine acetyl transferase PCAF, which may also contribute to transcriptional activation by the large E1A protein.²⁵⁹

The small and large E1A proteins through their common sequences can each stimulate G₀- and G₁-arrested cells to enter S-phase in the absence of other mitogenic signals such as serum growth factors.^{106,139,142} Presumably, this reflects the situation when Ad2 and Ad5 initiate an infection of a human host by infecting end-differentiated, G₀-arrested upper respiratory tract epithelial cells. Induction of cellular DNA synthesis requires E1A protein interactions with the abundant, closely related nuclear lysine acetyl transferases p300 and CBP (KAT3B, KAT3A)¹⁴² and the retinoblastoma family proteins RB1, RBL1 (p107), and RBL2 (p130)^{17,20,82,83,142,187,371,372} (Fig. 55.13). E1A proteins must form a trimeric complex between an RB-family protein, E1A, and p300 or CBP to oncogenically transform primary baby rat kidney cells.³⁶¹ A model of the trimeric structure has been presented⁹³ based on the structures of the complexes between Ad2/5 E1A residues 54 to 82 with the TAZ2 domain of CBP,⁹³ residues 37 to 49 with the cleft between cyclin folds in the RB1 pocket domain¹⁹⁷ and the LxCxE-containing peptide of HPV E7 protein, homologous to E1A CR2, with a complementary groove on the side of the C-terminal cyclin fold in the RB1 pocket domain¹⁷⁸ (Fig. 55.14). The two interactions with RB-family proteins remove RB-family proteins from the E2F family of transcription factors that control genes required for entry into S-phase.^{17,92,197,348} The interactions of e1a with CBP and p300 and the RB-family members induce a global change in the localization of these transcriptional regulators throughout the host-cell genome.⁹²

In NIH-3T3 cells arrested in G₀ by culturing in media with 0.05% serum for 60 hours, the promoter regions of the cell cycle-regulated genes *Cdc6* and cyclin A controlled by E2F transcription factors are bound by the repressing E2F4 tran-

scription factor associated with RBL2 (p130), which is in turn associated with the histone deacetylation complex HDAC1/2-mSin3B.¹⁰⁶ The promoter regions are also associated with the Suv39H1 histone methylase transferase that methylates histone H3 lysine 9 (H3K9), generating binding sites for the repressive heterochromatin protein 1 (HP1).^{106,297} Expression of E1A led to loss of p130, replacement of the repressing E2F4 with activating E2Fs 1, 2, and 3 and acetylation of H3K9.¹⁰⁶ This was not observed with a mutant in the cysteine of the CR2 LxCxE-motif that does not bind RB-family proteins, demonstrating the importance of this interaction for displacing p130 from E2F4 and the association of the activating E2Fs 1, 2, and 3.¹⁰⁶ Furthermore, an E1A mutant (*dl26-35*) that cannot bind the histone acetyltransferase/chromatin remodeling TRRAP-PCAF-p400 complex¹⁰¹ eliminated the E2F4-p130 co-repressor complex and H3K9me₂, but did not induce acetylation of H3K9/14 or transcription of *Cdc6* and cyclin A and entry into S-phase.²⁹⁷ These results demonstrate that E1A induces cells to enter S-phase by reconfiguring chromatin structure both by displacing repressing E2F4 and its co-repressor p130 associated with HDAC1/2-mSin3B and Suv39H1, dependent on the interaction of CR2 with RB-family proteins, and by inducing H3 acetylation by the TRRAP-PCAF-p400 complex.^{106,297}

Genomic studies with an Ad5 mutant that expresses only small e1a revealed that, remarkably, small e1a associates with the promoters of most cellular genes in a specific temporal order either activating or inhibiting their expression so as to favor viral replication.⁹² In contact-inhibited, G₁-arrested primary human fibroblasts, between 2 and 6 hours postinfection small e1a associated with promoter regions of genes involved in inflammatory responses and responses to pathogenic organisms, amounting to ~20% of all cellular genes. At these early times postinfection small e1a also became associated with the promoter regions of genes involved in passage through the cell cycle, DNA, RNA, and protein synthesis, amounting to ~30% of all cellular genes. By 12 hours postinfection, association with these first two classes of genes diminished greatly and small e1a

FIGURE 55.14. Model for the trimolecular complex between E1A residues 37 to 129 with the RB1 pocket domain and the CBP TAZ2 domain. Ribbon diagrams of the RB1 pocket domain (*brown*), the TAZ2 domain of CBP (*blue*) and regions of E1A (*orange*) for which the structure has been determined in complex with the RB pocket domain or the CBP TAZ2 domain are shown. Linker regions of E1A that may be unstructured are shown as a *dashed orange line*. The structure of the complex between E1A residues 37 to 49 and the RB1 A domain was reported in,¹⁹⁷ between E1A residues 54 to 82 and the CBP TAZ2 domain in.⁹³ The structure of the LxCxE containing region in CR2 is based on the structure of the homologous LxCxE region of HPV E7 bound to the RB pocket domain reported in.¹⁷⁸ The sequence of CBP is diagrammed at the bottom with HAT representing the lysine acetyl transferase catalytic domain, TAZ2 protein interaction domain shown in *black*. (From Ferreón JC, Martinez-Yamout MA, Dyson HJ, et al. Structural basis for subversion of cellular control mechanisms by the adenoviral E1A oncoprotein. *Proc Natl Acad Sci U S A* 2009;106:13260–13265, with permission.)

became associated with the remaining ~50% of genes involved in differentiated cell functions.⁹²

Small e1 activated transcription of the ~30% of genes involved in cell cycling and macromolecular synthesis. Induction of these genes was associated with the removal of all three RB-family proteins from their promoter regions and acetylation of histone H3K18 at and downstream from their promoter regions.⁹² CBP and p300, which are primarily responsible for acetylating H3K18 *in vivo*,¹³⁹ became associated with these promoter regions. Induction of many of these genes was also observed in contact-inhibited human fibroblasts infected by wt Ad5,²²² indicating that their induction is primarily due to activities of the common regions of the E1A proteins. The ~20% of genes involved in inflammation and other defenses against pathogenic organisms bound by small e1a at early times were repressed, and became associated with both the p300 and CBP acetyl lysine transferases and the RB-family transcriptional repressors RB1 and RBL2 (p130).⁹² Repression of genes involved in innate immune responses and inhibition of cell cycling as well as induction of genes involved in metabolic pathways contributing to cell growth were also observed after infection of HeLa cells with wt Ad2.^{108,397} The observation that promoter regions of host genes involved in antiviral defenses became associated with RB, p130, p300, and CBP⁹² suggests that the trimeric complex of RB or p130, e1a, and p300 or CBP³⁶¹ associate with the promoters of host genes involved in cellular antiviral defenses, repressing their transcription. By

24 hours postinfection, RBL1 (p107) became associated with repressed host genes involved in differentiated fibroblast functions.⁹² Consequently, it appears that after e1a dissociates RB-family proteins from E2F4 and other transcription factors to induce S-phase and cell growth, it exploits the same RB-family proteins to repress antiviral response genes and differentiated fibroblast functions that would otherwise inhibit virus replication and spread to new host cells. Three additional, alternatively spliced E1A mRNA species designated 9S, 10S, and 11S accumulate later in the infectious cycle that contains the same 3'-exon, but have additional sequences spliced out of the 5'-exons.^{313,325} However, as yet no distinct functions have been described for their translation products.

The conserved C-terminal region of E1A, CR4 (Fig. 55.14), contains both a five-residue nuclear localization signal (NLS) at the very C-terminus²⁰⁵ and a transcription repression domain.³⁰⁷ Transcriptional repression results from binding of either of two closely related 48-kD cellular proteins named for this activity (CtBP1/2 for C-terminal binding protein 1/2) that bind to the highly conserved sequence PXDLS just N-terminal to the NLS in all primate adenoviruses.^{34,291} The *Drosophila* ortholog of CtBP was subsequently discovered to be a co-repressor that binds to the same PXDLS sequence in several *Drosophila* repressors that function during embryogenesis.²⁴⁰ Thus far, the significance of this interaction for adenovirus replication remains unclear, but the interaction is required for oncogenic transformation of primary rodent cells by Ad2 E1A and E1B.^{50,51}

Transcription of the Other Early Regions and Functions of the Encoded Proteins E3

Once the large E1A protein is expressed, it activates transcription of early regions E1B, E2 early, E3, and E4. The E3 promoter consists of a TATA-box and binding sites extending to ~200 bp from the transcription start site for transcription factors NF1, AP1, and the family of transcription factors called ATFs, comprised of homo- and heterodimers of basic-leucine zipper proteins.¹⁴⁵ In lymphoid cells, an NF- κ B site at ~145 is critical to E3 expression.³⁷⁶ E3 expresses several alternatively spliced mRNAs encoding proteins that inhibit innate and acquired immune responses to viral infection. Consequently, activation of E3 by NF- κ B, which activates multiple cellular genes involved in innate and acquired immune responses, likely functions in a regulatory feedback loop that protects the virus-infected cells from these host antiviral mechanisms. The functions of the E3 proteins are discussed in Chapter 56, Adenoviruses.

E1B

The E1B transcription unit maps immediately to the right of the E1A region and encodes two abundant spliced mRNAs called 13S and 22S encoding proteins, commonly referred to as E1B-19K and E1B-55K (Figs. 55.8 and 55.10). The E1B promoter is composed primarily of an Sp1 transcription factor binding site closely juxtaposed to a canonical TATA-box.³⁸³

Additional transcription factor binding sites in the 3'-end of the E1A transcription unit stimulate E1B transcription further,²⁵⁷ as does "transcriptional read-through" from the E1A region.²¹⁸

The two major E1B proteins inhibit p53-dependent induction of apoptosis by two different mechanisms. The level and activity of the tumor suppressor p53 are induced by the abnormal stimulation of cell cycling induced by the E1A proteins.^{73,202} Apoptosis is induced following infection with an E1B-19K mutant because of proteasomal degradation of the critical cellular antiapoptotic BCL-2 family member MCL-1.⁶¹ E1B-19K is homologous to cellular BCL-2 family proteins⁶² and functions as an antiapoptotic MCL-1 viral mimic. It binds to the proapoptotic BCL-2 family members BAK and BAX, preventing them from co-oligomerizing and forming pores in the outer mitochondrial membrane. In the absence of E1B-19K, formation of such BAK-BAX pores in the outer mitochondrial membranes of infected cells releases apoptogenic proteins such as cytochrome c and Smac/DIABOLO,⁶² leading to the activation of caspase-9 and -3 and the ensuing apoptosis program.³¹¹ This pathway is blocked in wild-type virus-infected cells by the sequestration of activated BAK and BAX by E1B-19K binding (Fig. 55.15).

p53 function is directly inhibited by the E1B-55K protein through multiple mechanisms. Like SV40 T-antigen, E1B-55K binds p53 directly,²⁸⁹ an observation that led to the discovery that p53 is a major tumor suppressor.¹⁸⁵ E1B-55K binds to the amino-terminus of p53, which also contains the p53 activation domain and the region bound by MDM2, the major

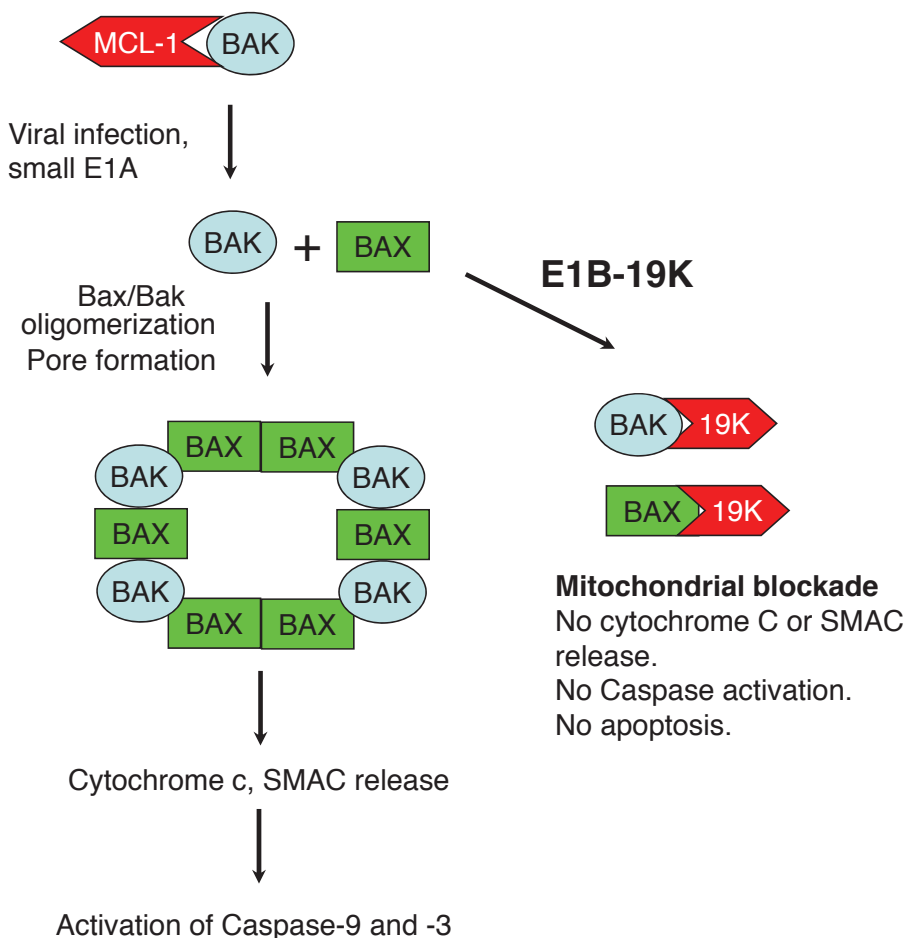

FIGURE 55.15. E1B-19K inhibition of pro-apoptotic BCL2 family members BAK and BAX. Infection of cells with an E1B-19K mutant, or expression of E1A proteins in the absence of other viral proteins results in the proteasomal degradation of MCL-1. This releases and activates BAK, which oligomerizes with BAX to form pores in the outer mitochondrial membrane. These pores release apoptogenic molecules such as cytochrome c and Smac. E1B-19K blocks this proapoptotic BCL-2 pathway by binding and sequestering BAK and BAX, preventing the formation of pores and the release of apoptogenic factors from mitochondria.³⁷⁰

ubiquitin ligase controlling p53 proteasomal degradation.^{157,190} As a result, p53 is stabilized and transcriptional activation by p53 is inhibited.^{387,388} The E1B-55K protein functions as a SUMO1 E3-ligase for p53²⁶⁰ resulting in the sumoylation of ~1% of p53 and association of the complex with PML-nuclear bodies.^{80,198,229,260} Sumoylation of a small fraction of a nuclear protein can result in the association of nearly all of the nuclear protein with PML-nuclear bodies.¹²⁷ In the case of the E1B-55K-p53 complex, this can be explained by the formation of a large network of p53 tetramers cross-linked by the binding of E1B-55K dimers²¹³ to the amino termini of p53 monomers in the p53 tetramers, and the binding of the small fraction of sumoylated E1B-55K^{84,377} and p53 by SUMO-interacting motifs in PML proteins, the major component of PML-nuclear bodies.^{260,377} Association of E1B-55K-SUMO1 complexes with PML-nuclear bodies promotes their nuclear export by exportin 1 (CRM1).^{163,173,260} In cells transformed by the integration of the E1A and E1B regions into cellular chromosomal DNA and when E1B-55K is expressed in the absence of other viral proteins, E1B-55K-p53 complexes exported to the cytoplasm are transported on microtubules by dynein motor proteins to the microtubule organizing center (MTOC) where they accumulate, forming large cytoplasmic inclusion bodies³⁹² called aggresomes.^{198,260}

E1B-55K protein also forms a complex with the E4orf6 protein that associates with cellular proteins Elongin B and C, cullin 5, and RBX1 to form an E3 ubiquitin ligase that poly-ubiquitinates p53, leading to its proteasomal degradation^{124,271} (Fig. 55.16). E1B-55K also binds the host cell MRE11-RAD50-NBS1 (MRN) complex through a distinct region from the E1B-55K region that binds p53.²⁹⁴ E1B-55K-MRN complexes also associate with PML-nuclear bodies and subsequently are exported to aggresomes at the MTOC.¹⁹⁸ The E1B-55K-E4orf6-Elongin B/C-cullin 5-Rbx1 ubiquitin ligase also poly-ubiquitinates subunits of the MRN complex, inducing their proteasomal degradation.³¹⁹ During infection, MRN complex and p53 are first inhibited by being sequestered in PML-nuclear bodies and then by their concomitant nuclear export and proteasomal degradation. Sequestration in PML-nuclear bodies and their subsequent nuclear export prevents them from interacting with nuclear substrates, and transport to the MTOC accelerates the rate of their degradation, probably because proteasomes and components of the ubiquitination pathway are concentrated at the MTOC.¹⁹⁸ The E1B-55K-E4orf6-containing ubiquitin ligase complex also targets other proteins involved in the dsDNA break response, including DNA ligase IV¹⁹ and the Bloom helicase,²⁴⁷ probably because the interaction of these proteins with the termini of adenovirus genomes would interfere with viral DNA replication. Another substrate of this viral ubiquitin ligase is integrin $\alpha 3$.⁶⁷ The degradation of this substrate may function to promote release and spread of progeny virions. E1B-55K and E4orf6 are also required for the inhibition of host mRNA nuclear export during the late phase of infection^{22,122,267} and a high rate of nuclear export of viral late mRNAs.^{122,267} The activity of the E1B-55K-E4orf6-containing ubiquitin ligase is also required for these activities,^{29,380} but the relevant substrate(s) remains to be identified.

E4

The E4 promoter extends at least 180 bp upstream of the major transcription start site and contains binding sites for at least

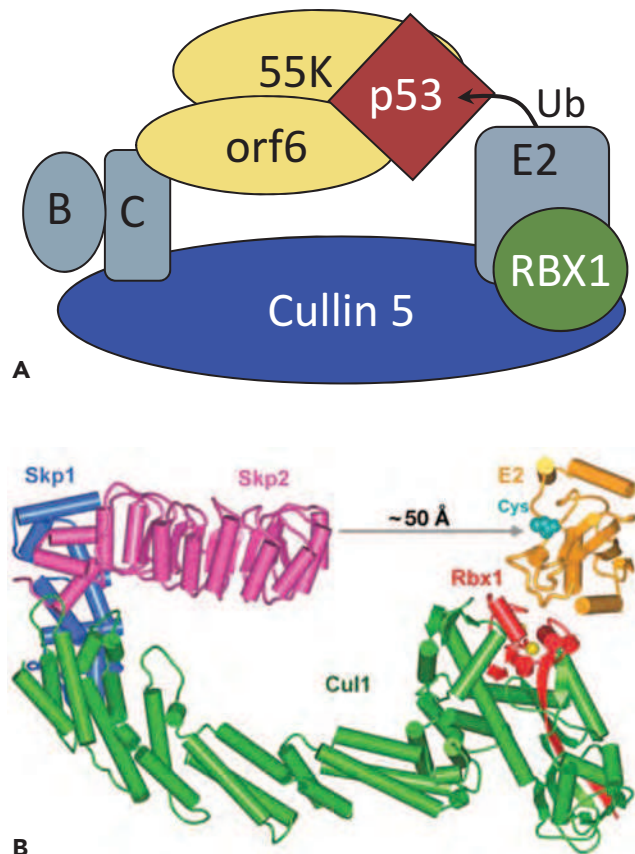

FIGURE 55.16. Diagram of the E1B-55K-E4orf6-Elongin B/C-RBX1 ubiquitin ligase complex. **A:** The Elongin B/C complex is bound to the N-terminus of Cullin 5, which interacts with the RBX1 protein through its C-terminus. E4orf6 binds to the Elongin C and E1B-55K interacts with E4orf6. An unknown E2(s) interacts with RBX1 and transfers ubiquitin to p53. The complex also induces degradation of the MRE11 subunit of the MRN complex,³¹⁹ DNA ligase IV,¹⁹ and the Bloom helicase.²⁴⁷ **B:** Model for the SCF cullin-based ubiquitin ligase complex³⁹⁸ on which the model in **A** is based. Skp2 is the substrate-binding subunit. (**A** adapted from Querido E, Blanchette P, Yan Q, et al. seven sequence-specific binding proteins in an HeLa nuclear extract.³⁶⁴ These include E4F,⁹¹ E4TF1,³⁶⁴ and the several basic-leucine zipper proteins collectively known as ATFs.^{121,356} Several alternatively spliced mRNAs are expressed from E4 that encode proteins named for the E4 ORFs in their order from 5' to 3'³⁵⁵ (Fig. 55.17).

E4orf1 and E4orf4 function to activate the protein kinase mTOR in the absence of nutrient and mitogenic signaling.²⁴⁸ Activated mTOR stimulates protein synthesis by phosphorylating and inhibiting 4EBP, which otherwise inhibits the eIF4E cap-binding translation initiation factor. Activated mTOR also phosphorylates and activates the protein kinase S6K, which stimulates translation by phosphorylating ribosomal protein S6, and additional targets that lead to increased synthesis of

FIGURE 55.17. E4 mRNAs and proteins.

Alternative splicing locates the first AUG of the leftwardly transcribed E4 open reading frames to the 5' end of the E4 mRNAs. E4orf7 is translated as a fusion with the 5' portion of orf6, generating the E4orf6/7 protein. Additional mRNAs not shown encoding E4orfs 1, 3, and 4 are also spliced to remove the intron that fuses orfs 6 and 7. But since this splice is 3' of the first open reading frames in these mRNAs, they do not alter the translated protein.³⁵⁵

ribosomes and translation factors.⁴⁰² Mitogens activate mTOR by activating phosphatidylinositol 3-kinase (PI3K) through a pathway involving Akt/protein kinase B, the tumor suppressor complex TSC1–TSC2, and the Ras-family GTPase Rheb that ultimately activates mTOR.⁴⁰² E4orf1 activates mTOR by activating PI3K through interactions with several host-cell PDZ-domain-containing proteins at the plasma membrane.^{56,100,248} Recently, it has been discovered that proteins encoded by many viruses interact with PDZ-domain-containing members of the membrane-associated guanylate kinase protein family, disrupting tight junctions between epithelial cells and, consequently, probably aiding in progeny virus dissemination.^{151,176} But the molecular mechanism by which E4orf1 binding to PDZ-domain proteins leads to potent PI3K activation is as yet not understood.

E4orf4 also activates mTOR by another mechanism that is independent of PI3K and Akt.²⁴⁸ E4orf4 binds to substrate-binding β subunits of the trimeric protein phosphatase PP2A family.^{167,211} This interaction is required for mTOR activation.²⁴⁸ How this interaction leads to mTOR activation is not understood, but it seems likely that alterations in the substrate specificity or activity of PP2A are involved.³⁹⁶

E4orf3, a small (11-kD) hydrophobic protein, inhibits induction of the cellular DNA double-stranded break response (DSBR), protecting the termini of the viral genome. It does so by sequestering the cellular MRN complex and p53 in nuclear bodies with PML protein that have altered morphology, often described as track-like, compared to PML nuclear bodies in uninfected cells.^{86,309,319} Recall that E1B-55K also inactivates the MRN complex and p53 by itself and as the substrate binding subunit of the E1B-55K–E4orf6 ubiquitin ligase complex that induces the degradation of MRN subunits. Consequently, adenovirus employs several independent mechanisms to inactivate p53 and the MRN complex that otherwise interfere with viral DNA replication. E4orf3, like E1B-55K, also induces nuclear export of MRN complex subunits to cytoplasmic aggresomes.¹³ These processes inhibit MRN complex activation of the ATR protein kinase that otherwise activates the DSBR.⁴¹ E3orf3 also induces histone H3 lysine 9 methylation of p53 target promoters, inhibiting their binding by p53.³⁰⁹

E4orf3 is particularly important for counteracting the antiviral interferon response by inhibiting innate antiviral functions of PML nuclear bodies mediated by PML and the associated host cell Daxx protein.³⁴⁷ E4orf3 also localizes components of cytoplasmic P-bodies, sites of translation inhibition and mRNA degradation, to aggresomes, potentially accounting for E4orf3's stimulation of late viral mRNA accumulation and late protein synthesis.¹¹⁴

The fifth short ORF originally identified in the Ad2 E4 sequence¹³¹ is apparently not translated. E4orf6 was discussed earlier in the context of the E1B-55K–E4orf6–Elongin B/C–Cul5–Rbx1 ubiquitin ligase complex. E4orf6 also interacts with and inhibits p53 independently of E1B-55K.⁷⁸ E4orf6,^{133,312} but not E1B-55K,^{212,312,374} also can bind to p73 and inhibits its function. The p73 protein is a member of the p53 family that is able to activate transcription through p53 response elements. It is transcriptionally induced by small E1A, probably through E2F binding sites associated with one of its two alternative promoters.⁹⁶ Thus, E4orf6 antagonizes the function of both p53 and p73, blocking their potential inhibitory effects on viral replication.

E4orf7 is expressed as a fusion with the N-terminal region of E4orf6 generated by RNA splicing and translation of a protein called E4orf6/7 (Fig. 55.17). E4orf6/7 forms a dimer that binds to and effectively dimerizes cellular E2F transcription factors, greatly increasing their affinity for the E2 early promoter by cooperative binding to the appropriately spaced inverted E2F binding sites.^{215,233,245}

E2

Transcription of the E2 region peaks after the other early regions,²³⁷ and while the other early regions continue to be transcribed throughout the late phase of infection, E2 transcription reaches much higher levels than the other early regions, in part because of the activation of a second E2 promoter, the E2 late promoter⁵⁴ (Fig. 55.8). The E2 early promoter is composed of two binding sites for the E2F family of transcription factors in inverted orientation upstream of a noncanonical TATA-box as well as a binding site for the E1A-EF transcription factor just upstream of these.^{172,302} The E2 late promoter extends

~160 bp upstream from the transcription start site and includes a noncanonical TATA-box and binding sites for two Sp1 transcription factors and two CCAAT boxes that can be bound by several CAAT-box binding factors.²⁷

E2 encodes the three viral proteins required for adenovirus DNA replication, the preterminal protein (pTP) which primes DNA synthesis at the 5' end of each daughter strand, the Ad DNA polymerase (Ad Pol), and the Ad ssDNA binding protein (DBP). DBP, encoded in the E2A region, is required in much larger amounts than the Ad Pol or the pTP encoded in the E2B region (Fig. 55.8). Much more of the E2A mRNAs, which both encode DBP, are expressed than the E2B mRNAs as the result of alternative cleavage and polyadenylation of the E2 primary transcript most frequently at the E2A polyA site near 62 map units. However, some of the E2 primary transcripts are spliced from the second E2 exon at 68 map units to the 5' end of a third exon at 39 map units and then to a fourth pTP mRNA exon at 29 map units or the fourth Ad Pol 3' exon at 23 map units, splicing the E2A polyA site out of the pre-mRNAs (Fig. 55.8). Translation of these mRNAs begins at an AUG in the third exon at 39 map units and continues into the open reading frame that encodes most of the pTP in the longer E2B mRNA or the open reading frame that encodes most of the Ad Pol in the shorter of the E2B mRNAs.²⁹⁹ The E2B mRNAs utilize the same polyA site as the IVa2 mRNA expressed at intermediate times postinfection.³¹⁷

It is remarkable that adenovirus regulates the expression of the viral proteins required for viral DNA replication in part by activating the same E2F family of transcription factors that regulate cellular genes required for entry into S phase. This economical arrangement by which E1A activates both viral and cellular genes probably evolved to coordinate the timing of viral DNA synthesis with the activation of cellular genes required for synthesis of deoxyribonucleotide triphosphates and other aspects of cell physiology conducive to DNA replication.

LATE TRANSCRIPTION

During the early phase of infection, the major late promoter (MLP) at 17 map units is active, but only the longest L1 mRNA encoding the 52/55K protein is expressed.²⁹⁸ Adenovirus late genes encoding virion polypeptides, and the L4-100K protein (Fig. 55.11) involved in late-phase translational regulation and virion assembly (see Regulation of Translation and Virion Assembly) begin to be expressed efficiently at the onset of viral DNA replication. The adenovirus late coding regions are organized into a single large transcription unit with the MLP at 17 map units and a length of ~28 kb.^{236,401} This transcript is processed by differential poly(A) site utilization and splicing to generate at least 14 distinct mRNAs (Fig. 55.8). These mRNAs are grouped into five families, termed L1 to L5, based on the use of common poly(A) addition sites.^{54,236,400} Each family consists of alternatively spliced mRNAs that all contain a 201-nucleotide untranslated tripartite leader generated from the splicing of three short exons (1, 2, and 3, Fig. 55.8)^{3,24,53} to a longer exon containing an open reading frame that generally is not interrupted by introns, except in the case of the L4-33K mRNA (Fig. 55.11). Different open reading frames in each late mRNA family are accessed by alternative RNA splicing of the 3' end of the third tripartite leader exon to different splice sites that define the 5' end of the longer, protein-coding 3' exon (Figs. 55.8 and 55.11). The 5' leader in the L1-53/55K mRNAs expressed at early times also

contains an additional 440 nucleotide exon called the i-leader (Fig. 55.8) that encodes a 135 amino acid protein. That protein is not required for viral replication in cultured cells, but the presence of the i-leader dramatically reduces the half-life of L1 mRNAs from ~26 hours for L1 mRNAs lacking the i-leader to ~4 hours for L1 mRNAs containing the i-leader.³⁰⁸

Expression of this large family of late mRNAs is controlled by the major late promoter (MLP). This promoter exhibits a low level of activity early after infection, but becomes several hundred-fold more active on a per DNA molecule basis at late times.²⁹⁸ There appear to be at least two distinct components that contribute to the delayed activation of the major late promoter: a *cis*-acting change in the viral chromosome dependent on viral DNA replication,³³⁴ and expression of two virus-coded transacting factors at intermediate times postinfection. As yet, there is no molecular explanation for the requirement for viral DNA replication. The IVa2^{256,343} and L4-22K^{16,226,250} proteins greatly stimulate transcription from the MLP by binding to sites in the first intron between leader exons 1 and 2.^{16,182,250,343} These two proteins also bind cooperatively to repeated sequences at the left end of the genome, promoting packaging of viral DNA into subviral particles (see Virion Assembly). IVa2 is transcribed at intermediate times postinfection dependent on initiation of viral DNA replication²⁸ from a TATA-less promoter with a strong initiator sequence that determines the transcription initiation site¹⁵⁹ and additional control elements downstream within the IVa2 coding region.⁴⁶ IVa2 then activates a TATA-less promoter upstream of the L4-22K and L4-33K coding region, within the 100K coding region, stimulating expression of the L4-22K and L4-33K proteins and transcription from the MLP.²²⁶ L4-22K also stabilizes the IVa2 protein, resulting in a positive feedback loop that increases the expression of both proteins and results in a rapid increase in MLP transcription at the initiation of viral DNA synthesis.²²⁶ The requirement for viral DNA replication for expression of IVa2 and L4-22K delays activation of the MLP and expression of the virion structural proteins until they are needed for packaging of replicated viral DNA. L4-22K also stimulates transcription from the IX promoter (Fig. 55.8), contributing to activation of this promoter at intermediate times postinfection.¹⁶

REGULATION OF TRANSCRIPTION ELONGATION AND RNA SPLICING DURING THE LATE PHASE

Two viral proteins—E4orf4 which, as discussed previously, binds to protein phosphatase 2A complexes, likely altering their substrate specificity,^{36,396} and L4-33K³⁴¹—remodel the host cell splicing machinery to modify the splicing of viral pre-mRNAs and probably host-cell pre-mRNAs during the late phase. During the early phase, transcription from the MLP generates only mRNA with the L1 polyA site encoding the 52K/55K protein.^{2,238} During the late phase, mRNAs are synthesized from all five late families using one of five alternative polyA sites (Fig. 55.8), and splicing of L1 pre-mRNA to the downstream alternative 3' splice site generates the protein IIIa mRNA.^{2,175,238}

The early 52/55K 3' splice site is a much better fit to the mammalian consensus 3' splice site sequence than the IIIa splice site. It contains a long polypyrimidine tract, which is a binding site for the essential U2AF splicing factor that recruits the U2snRNP to the pre-mRNA splicing branch point. The L4-33K protein functions through the sequence immediately upstream of the IIIa 3' splice site, functioning as a splicing

enhancer that induces splicing to this site.³⁴¹ Early in infection, host-cell SR proteins bind to a sequence just upstream from the IIIa branch point A, blocking binding of the U2snRNP to the IIIa splice site.^{69,155} Dephosphorylation of host SR proteins dependent on Eforf4 relieves this inhibition of IIIa splicing.¹⁵⁶ Since the phosphorylation of SR proteins is required for their association with consensus splicing signals, the dephosphorylation and inactivation of SR proteins probably contributes to the inhibition of host-cell gene expression during the late phase.¹⁵⁶ Several other 3' splice sites in the MLP pre-mRNA with short polypyrimidine tracts also are activated during the late phase of infection, probably through similar mechanisms to the control of the IIIa 3' splice site.¹ At present, the molecular mechanism(s) that prevents RNA polymerase II elongation to the end of the genome during the early phase is poorly understood, as is the mechanism that relieves this inhibition of elongation during the late phase. However, together with the activation of the MLP by proteins IVa2 and L4-22K and the regulation of 3' splice site selection by proteins E4orf4 and L4-33K, prodigious amounts of the late mRNAs are expressed at appropriate high concentrations to serve as mRNAs for translation of the large amounts of virion structural proteins required for the generation of ~100,000 virion particles per infected HeLa cell.

REGULATION OF TRANSLATION

During the early phase of infection, viral early mRNAs are translated along with the continued translation of host-cell mRNAs. However, during the late phase of infection, translation of host-cell mRNAs is inhibited and virtually all of the host-cell translation apparatus becomes dedicated to translating the late viral mRNAs, especially mRNAs processed from the MLP pre-mRNA with the 5' untranslated sequence generated by the splicing of exons 1, 2, and 3 to generate the 201-bp tripartite leader sequence that precedes the initiation codon. Translation initiates at the first AUG downstream from the tripartite leader, so that splicing of exon 3 to the alternative 3' splice sites in the L1 to L5 mRNA families accesses the coding regions for each of the virion structural proteins and the L4 proteins not incorporated into the virion (L4-100K, -33K and -22K).

In addition to their facilitated transport from the nucleus to the cytoplasm discussed earlier,²² late after infection viral mRNAs are preferentially translated when they reach the cytoplasm.⁶⁴ During this period, when viral mRNAs constitute about 20% of the total cytoplasmic pool,³²⁶ they are translated to the exclusion of host mRNAs.¹⁵ The inhibition of host mRNA translation results from dephosphorylation of the translation initiation factor that binds the 5'-m⁷GpppN cap structure on most cellular mRNAs, eIF4E.¹⁴³ eIF4E is a subunit of the multimeric initiation factor eIF4F that includes a large scaffold subunit, eIF4G, to which are bound the cap-binding subunit eIF4E and eIF4A, an RNA helicase, as well as other proteins. The entire complex functions as a cap-dependent RNA helicase that unwinds secondary structure at the 5' ends of mRNAs and promotes binding of the 40S ribosomal subunit and scanning of the 40S ribosomal subunit to the translation initiation codon.¹⁵⁰ Dephosphorylation of eIF4E reduces cap-dependent translation by reducing the interaction of eIF4F complexes with capped mRNA.

In uninfected cells, eIF4E is phosphorylated by the protein kinase Mnk1 when both are bound to the same molecule of eIF4G. During the late phase, the N-terminus of the abundantly

expressed L4-100K protein (Figs. 55.8 and 55.11)²⁴⁷ binds to eIF4G, displacing the Mnk1 kinase, resulting in dephosphorylation of eIF4E by an unopposed phosphatase.^{63,65} Late viral mRNAs transcribed from the major late promoter continue to be translated because of the 201-base 5' tripartite leader sequence generated from the three short exons spliced to their coding exons (Figs. 55.8 and 55.9).^{25,79,199} The tripartite leader overcomes the inhibition due to hypophosphorylation of eIF4E by two mechanisms. First, the tripartite leader promotes an alternative form of translation initiation, referred to as ribosome shunting.³⁹¹ Rather than scanning from the 5' cap through the 5' untranslated region to the initiation codon, the 40S ribosomal subunit initially binds to the 5' cap, then is directly transferred to the initiation codon without scanning through the tripartite leader 5' untranslated region. Ribosome shunting is largely dependent on three regions of the tripartite leader that are complementary to the 3' end of 18S rRNA, evoking a mechanism of translation initiation similar to that in bacteria.³⁹¹ Similar complementarity between the 5' untranslated region of the IVa2 mRNA and 18S ribosomal RNA also promotes ribosome shunting and maintains IVa2 translation during the late phase.³⁹¹

In addition to the primary (and probably also the tertiary) structure of the tripartite leader, L4-100K is required for the stimulation of translation by the tripartite leader during the late phase.¹²⁸ 100K binds both the tripartite leader^{384,385} and the eIF4G scaffold subunit of eIF4F, thereby directly stimulating ribosome shunting.³⁸⁵ The tripartite leader also stimulates late mRNA export from the nucleus during the late phase, possibly through an interaction with 100K.¹⁴⁴ The multifunctional 100K protein also functions as a chaperone in the folding of the trimeric hexon protein, encoded by the most abundant late mRNA. Interaction with the cap structure puts it at high local concentration during the synthesis of hexon.

VAI AND VAII TRANSCRIPTION BY RNA POLYMERASE III

The small, abundant VA RNAs were named when their viral origin was still uncertain.²⁷⁶ Different adenovirus types encode one or two VA RNAs; Ad2 and Ad5 encode two species, termed VAI and VAII. The VA RNAs are each about 160 nucleotides in length, are GC rich, adopt stable secondary structures that are important for their function, and are transcribed by RNA polymerase III³⁶⁹ from an internal promoter with A- and B-boxes similar to those of transfer RNA (tRNA) genes.^{97,115} VA RNA synthesis begins during the early phase of the infectious cycle and dramatically accelerates during the late phase as the viral DNA template replicates. VAI accumulates to about 10⁸ molecules per infected HeLa cell, roughly the abundance of ribosomes, and VAII reaches about 10⁷ molecules per cell.

The initial indication of the function of VA RNAs came from analysis of a mutant Ad5 virus in which the VAI gene was deleted.³³³ The virus grew poorly, and its defect was traced to inefficient protein synthesis during the late phase of infection. Additional work identified a defect in polypeptide chain initiation^{277,293} resulting from phosphorylation of the eukaryotic initiation factor-2 (eIF-2) α -subunit.^{277,292} eIF-2 binds to guanosine triphosphate (GTP) and the initiator tRNA to form a ternary complex, which then interacts with the 40S ribosomal subunit. When the 40S ribosomal subunit binds the initiating AUG, eIF-2 hydrolyzes the GTP to GDP and leaves the 40S subunit with the initiator tRNA in the ribosomal P site.

Subsequent steps in the initiation process involving additional factors result in the binding of the 60S ribosomal subunit and chain elongation.¹⁵⁰ For eIF-2 to participate in another round of initiation, its GDP must be replaced with GTP in a reaction catalyzed by eIF-2B, a guanosine nucleotide exchange factor. The exchange reaction is inhibited by phosphorylation of the α subunit of eIF-2. The eIF-2- α (P) forms a tight complex with eIF-2B, preventing it from cycling and catalyzing the exchange reaction. As a result, initiation is brought to a halt when about one-third to one-half of eIF-2 is phosphorylated, trapping all available eIF-2B.

Phosphorylation of eIF-2 is mediated by the cellular protein kinase PKR. Synthesis of an inactive form of PKR is induced by interferon, and the latent enzyme that can phosphorylate eIF-2 α is activated by dsRNA. PKR is activated by autophosphorylation, which appears to require that two molecules of the enzyme interact with one molecule of dsRNA.¹⁷⁰ VAI folds into a structure with extensive base pairing that binds PKR, blocking rather than stimulating its activation.^{160,165,242} As a result, VAI RNA blocks the antiviral effect of dsRNA generated from transcription of both strands of the viral genome during the late phase and blocks the antiviral effect of interferon.¹⁶⁵

In contrast to VAI, VAI exhibits limited ability to block PKR activation. However, both VAI and VAI inhibit the processing of cellular micro RNAs (miRNAs). miRNAs are ~22 nucleotide RNAs incorporated into RNA silencing complexes (RISC) that inhibit translation of mRNAs to which they base pair with a small number of base-pair mismatches.⁵ They are transcribed as long precursors called pri-miRNAs and processed by the nuclear enzyme Drosha into ~65 nucleotide stem-loop RNAs called pre-miRNAs. pre-miRNAs are exported from the nucleus to the cytoplasm, where they are further processed by the ribonuclease Dicer into the ~22 nucleotide miRNAs incorporated into RISC complexes. RISC complexes can also be programmed by transfected siRNA with the characteristics of products of Dicer digestion: ~22 bp dsRNAs with two base 3' single-stranded regions. When the siRNA in an RISC complex hybridizes to perfectly complementary regions of an mRNA in vertebrate cells, the RISC complex cleaves the mRNA, initiating its rapid degradation by exonucleases.⁸¹

VA RNAs are synthesized in the nucleus and transported into the cytoplasm by exportin-5.^{119,389} This same exportin transports pre-miRNAs from the nucleus to the cytoplasm, where they are processed into miRNAs by Dicer. During the late phase of infection, the abundantly expressed VA RNAs interfere with the nuclear export of pre-miRNAs by competing with them for binding to exportin-5.²⁰³ VA RNAs in the cytoplasm also bind to Dicer and competitively inhibit pre-miRNA processing.^{10,203} Specific ~22 nucleotide fragments of the VA RNAs are incorporated into RISC complexes that are functional, but do not target viral mRNAs because the VA RNAs are transcribed from the region of the genome that encodes introns from the major late and E2B transcription units (Fig. 55.8).¹⁰ The competitive inhibition of pre-miRNA nuclear export and cytoplasmic processing by VA RNAs interferes with the expression of cellular miRNAs. Since Dicer is a critical enzyme in processing dsRNA into miRNAs and siRNAs, the VA RNAs are expected to interfere with endogenous miRNA interference, and any siRNA interference that might otherwise result from dsRNAs generated by hybridization of

viral pre-mRNAs in the nucleus. However, as of now, it is not clear to what extent the inhibition of the miRNA and siRNA processing pathway contributes to the success of an adenovirus infection.

Viral DNA Replication

As E2 gene products accumulate in response to transcriptional activation of the E2 early promoter by large E1A and stimulation of E2F transcription factor binding by E4orf6/7 as described previously, the stage is set for viral DNA replication. Ad2 and Ad5 DNA replication begins ~6 hours after infection of HeLa cells at a multiplicity of 10 plaque-forming units per cell, and it continues until the host cell dies.

Adenovirus DNA replication occurs by a mechanism requiring a minimal set of replication proteins: the pTP terminal protein primer of DNA synthesis, the viral DNA polymerase, Ad Pol, and the ssDNA binding protein, DBP. The inverted terminal repeats of the viral chromosome serve as replication origins. Viral DNA replication takes place in two stages¹⁷⁷ (Fig. 55.18). First, synthesis is initiated at either terminus of the linear DNA and proceeds in a continuous fashion to the other end of the genome. Only one of the two DNA strands serves as a template for the synthesis; thus, the products of this stage of replication are a duplex consisting of a daughter and parental strand plus a displaced single strand of parental DNA. In the second stage of the replication process, a complement to the displaced single strand is synthesized. The single-stranded template circularizes through annealing of its self-complementary termini that result from the inverted terminal repeat at the ends of the genome. The resulting duplex "panhandle" in the otherwise single-stranded circle has the same structure as the termini of the duplex viral genome. This structure allows it to be recognized by the same initiation machinery that operates in the first stage of replication, and complementary strand synthesis generates a second completed duplex consisting of one parental and one daughter strand. Adenovirus DNA was the first eukaryotic DNA to be replicated *in vitro*,⁴⁴ and increasingly defined *in vitro* replication systems allowed analysis of replication in considerable detail.

The *cis*-acting sequences composing the replication origins are located within the inverted terminal repeats of the viral chromosome. Three functional domains have been defined within the terminal 51 bp of the repeats. Domain A consists of the first 18 bp of the viral DNA, and it functions as a minimal origin of replication. This domain is required for replication but supports only limited replication on its own. The sequence between base pairs 9 to 18 (5'-ATAATATACC-3') is conserved among different human adenovirus types, and a complex of two viral proteins binds here: the preterminal protein (pTP) and the DNA polymerase.^{48,227,332} The E2B-coded terminal protein (TP) is synthesized as an 80-kD polypeptide (pTP) that is active in initiation of DNA replication^{43,85,147,317} and, as discussed previously, is found covalently attached to the 5' ends of the viral chromosome. It is subsequently processed by proteolysis at three sites during assembly of virions to generate a 55-kD fragment (TP) that is covalently attached to the genome, but it appears that the entire protein with cleaved peptide bonds remains associated with the genomic termini.²⁹⁰ The E2B-encoded DNA polymerase (AdPol) is a 140-kD protein^{94,318} in the eukaryotic Pol α family.^{149,195} Like other Pol α s, AdPol contains both 5' to 3' DNA polymerase activity and 3'

FIGURE 55.18. Simple mechanism of adenovirus DNA replication.

The parental strands are at the top. The strand transcribed to the left is the l-strand (blue); to the right, the r-strand (gray). The ends of the genome are identical because of the genome inverted terminal repeat (102 base pairs in Ad2). Replication beginning on the left end is shown on the left; beginning at the right end on the right. Arrowheads represent 3' ends. Replication occurs in two stages: synthesizing the entire length of one strand first (Stage 1), and the entire length of the complementary strand is synthesized second (Stage 2). With replication beginning at the left, daughter l-strand (red) remains base-paired to the r-strand template, while the parental l-strand is displaced as a single-stranded DNA (bound by the viral DBP, which is not shown). Replication is primed by the pTP protein (not shown) covalently bound to dCMP whose 3'-OH group is extended by the Ad Pol. The entire l-strand is displaced as a single stranded DNA when l-daughter strand synthesis proceeds to the end of the genome. Because of the inverted terminal repeat, the left and right end of the displaced, single-stranded parental l-strand base pair over the length of the repeat, generating a double-stranded region (a "panhandle") identical to the end of the parental genome. Priming of DNA replication and extension of the r-daughter strand reaches the end of the duplex region of the panhandle, breaking the interaction between the ends of the parental l-strand and generating a linear DNA that is partially single stranded with a growing r-daughter strand. Extension of the r-daughter strand completes the synthesis of two double-stranded DNA daughters of the parental DNA with one newly synthesized daughter strand. Replication from the right end (right) proceeds by the same mechanism for the complementary strands. Note that unlike the mechanism for replication of most other DNA molecules, lagging strand synthesis does not occur as short (Okazaki) fragments that are ligated together. The adenovirus mechanism requires only three proteins: pTP, Ad Pol, and DBP. (Adapted from Lechner RL, Kelly Jr. T.J. The structure of replicating adenovirus 2 DNA molecules. *Cell* 1977;12:1007–1020.)

to 5' exonuclease activity, which serves a proofreading function during polymerization.^{94,164} The pTP and the polymerase form a heterodimeric complex in solution that binds to the conserved base pair 9-18 sequence in origin domain A.^{85,188,318,332}

Two more binding sites in the left end of the terminal repeat that are bound by host-cell transcription factors NF1^{31,48,228} and OCT1^{228,243,269} are not absolutely required for adenovirus DNA replication, but they substantially enhance the efficiency of the initiation. The DNA-binding domain of NF1 interacts with AdPol^{48,228} and the DNA-binding domain of Oct-1 binds to the pTP.^{32,350} The binding of NF1 at domain B is stimulated by the third viral protein that functions in DNA replication, DBP.^{57,322} The resulting protein–DNA and protein–protein interactions stabilize binding and properly position the pTP–AdPol complex at the origin. Consequently, the preinitiation complex is composed of the terminus of the viral DNA bound by three viral proteins, pTP, AdPol, and DBP, and two host-cell transcription factors, NF1 and OCT1.

As a protein primer, pTP preserves the integrity of the viral chromosome's terminal sequence during multiple rounds of DNA replication. The priming reaction begins with the formation of an ester bond catalyzed by the AdPol between the β -OH of a serine residue in pTP (serine 580)³⁰³ and the α -phosphoryl group of deoxycytidine monophosphate (dCMP), the first residue at the 5' end of the DNA chain.^{43,189} pTP melts the end of the DNA duplex, allowing the template strand to enter the active site of the polymerase.⁷² The 3'-OH group of the pTP–dCMP complex then serves to prime synthesis of the nascent strand by AdPol. Replication and late transcription take place in large nuclear domains called replication centers.³⁷ pTP-binding to the CAD enzyme, which catalyzes three steps in pyrimidine synthesis,¹¹ and association with the poorly soluble nuclear matrix fraction,^{98,290} may localize the replicating DNA to microenvironments in the nucleus where dNTPs are synthesized²⁵⁵ and may help to localize the viral replication centers.

Chain elongation requires the virus-encoded AdPol and DBP, as well as cellular topoisomerase I.²³¹ The abundantly expressed virus-coded DNA-binding protein is a 59-kD phosphoprotein that migrates in SDS-polyacrylamide gels with an apparent molecular weight of 72 kD. It binds tightly and cooperatively in a sequence-independent fashion to ssDNA.³⁴⁹ The three-dimensional structure of the larger C-terminal DBP DNA-binding domain sufficient for *in vitro* replication was determined by x-ray crystallography.³⁴⁵ The DBP C-terminal extension has a flexible hinge that hooks onto an adjacent DNA-binding protein monomer. This drives the formation of long, multimeric protein chains bound to ssDNA. Polymerization of the DNA-binding protein on ssDNA drives strand separation, consistent with the lack of a requirement for a DNA helicase to unwind the double-stranded template at the growing fork in reconstituted adenovirus DNA replication reactions.⁷⁴ In the presence of DBP, AdPol is highly processive and can travel the entire length of the chromosome after it has separated from pTP.⁹⁴ Topoisomerase I enhances the synthesis of nascent chains >9 kb long; hence, it must be needed to overcome a DNA structural problem that arises only after extensive replication.

In summary, a set of proteins has been identified that mediates the initiation of adenovirus DNA replication (pTP, AdPol, DBP, NF1, and OCT1) and chain elongation (AdPol, DBP, and topoisomerase I). These polypeptides, together

with a template containing an adenovirus replication origin, are sufficient to reconstitute the complete viral DNA replication reaction *in vitro*. The simplicity of this DNA replication mechanism and the location of the viral DNA packaging sequences at the left end of the genome allowed the development of helper-dependent adenovirus vectors in which nearly all of the viral DNA is substituted with other DNA sequences of interest, while the proteins required for DNA replication and the packaging of vector DNA are supplied by a helper virus genome with its packaging sequence removed.^{136,258}

Virion Assembly

The replication of viral DNA, coupled with the production of large quantities of the adenovirus structural polypeptides, sets the stage for virus assembly. In addition to suppressing the translation of host-cell mRNAs and stimulating the translation of viral late mRNAs with the tripartite leader, L4-100K acts both as a chaperone to facilitate the folding of hexon and as a scaffold to facilitate assembly of trimers.¹³⁸ Penton capsomeres consisting of a pentameric penton base and trimeric fiber assemble in the cytoplasm, subsequently joining to form a complete penton capsomere.^{140,354} After their production, hexon and penton capsomeres are imported into the nucleus, where assembly of the virion occurs.

Ad DNA is packaged into capsids in a polarized fashion starting at the left end of the genome.^{68,123,129,335} Extensive mutational analysis showed that seven AT-rich sequences with the consensus sequence 5'-TTTG-N₈-CG-3' located between Ad5 bp 200 to 400 function in viral DNA encapsidation.²⁵³ This ~200-bp packaging sequence also functions in virion assembly when placed at the right end of the genome, but must be within ~600 bp of an end.¹²⁹ Results from mutational studies of the packaging sequence, *in vitro* DNA-protein binding studies, and chromatin immunoprecipitation assays of infected cells indicate that the viral IVa2, L4-22K, and L1 52/55K bind the packaging sequence and promote viral DNA packaging into pro-capsids.^{88,250,252,262,395} Mutants of both IVa2³⁹⁵ and 52/55K^{117,126} are defective for virion packaging. IVa2 appears to provide the sequence specificity for binding to the packaging motifs,^{88,254,262,346,394} while 52/55K makes specific protein-protein interactions with IVa2.^{88,118} Protein IIIa also associates with empty capsids, interacts with the 52/55K protein, and participates in the packaging process.²⁰⁶ IVa2 and L4-22K also function in late-phase activation of the MLP (see Late Transcription) where they bind sequences similar to the repeated AT-rich repeated packaging sequence in transcription control elements in the first intron of the late mRNAs.

Analysis of the IVa2 sequence from human and nonhuman adenoviruses showed that they contain conserved Walker A- and B-box consensus sequences found in ATPases.¹⁶⁹ Consistent with this, IVa2 binds ATP²⁵¹ and mutation of the conserved lysine in the Walker A-box required for activity of ATPases resulted in loss of viability.²⁵⁶ Significantly, IVa2 is associated with one vertex of the mature virion particle.⁵⁵ Thus, IVa2 functions as an ATP-driven motor for inserting viral DNA into a pro-capsid, as observed for large bacteriophage.¹⁶⁹ 52/55K mutants assemble empty capsids,^{117,125,395} while a IVa2 null mutant assembles unstable empty particles.^{95,395} Similarly, deletion of the packaging sequence to which IVa2 binds prevents the appearance of empty capsids.¹²⁹ A temperature-sensitive 52/55K mutant accumulates the mutant protein in

particles containing ~1 kb of viral DNA from the left end of the genome,¹²⁵ but the wild-type protein is not found in mature virions. These results indicate that 52/55K assists a IVa2 packaging motor in stuffing viral DNA into the capsid.

The major histone-like virion core protein VII is synthesized as a precursor, pVII,⁷ that associates with viral DNA during the late phase.^{38,366} pVII interacts with IVa2 and 52/55K.³⁹³ Consequently, viral DNA—with its associated preterminal proteins—is packaged as a complex with pVII and the other virion core proteins V and a precursor of μ .^{366,393}

Finally, cleavage of the precursors of proteins VI, VII, VIII, μ , and terminal protein by a viral protease included in the particles completes assembly of infectious virions. The L3-coded 23-kD viral protease,³⁶⁷ a cysteine protease that requires DNA and a C-terminal fragment of pVI as cofactors,^{77,116,210,336,368} functions late in the assembly process. Its activity is required for removal of 52/55K protein from maturing capsids¹²⁵ as well as maturation of the virion proteins. These cleavages stabilize the particle and render it infectious. A mutant virus with a defective L3-coded protease accumulates noninfectious, virion-like particles with a set of unprocessed polypeptides.³⁶⁵ The requirement of DNA and a pVI fragment for activity of the protease prevents it from processing precursors until both the protease and the precursors are incorporated into maturing virion particles. As discussed in the section on Adsorption and Entry, virion-associated L3 protease activity is also required for uncoating during the process of infection.¹¹¹

Virus Release

There are several processes that facilitate the release of progeny virions from infected cells and the spread of progeny virus in infected tissues. Late in the infectious cycle, the L3-23K viral protease cleaves the cellular cytokeratin K18.⁴⁹ This cleavage event occurs at amino acid 74 of the cytokeratin, creating a "headless" protein that is not able to polymerize and form filaments; rather, it accumulates in cytoplasmic clumps. A normal intermediate filament system helps to maintain the mechanical integrity of cells, and perturbations to the network would be expected to make the infected cell more susceptible to lysis.

The second system that facilitates the release of progeny virions involves the E3 11.6-kD protein. This protein, which is also referred to as the adenovirus death protein, kills cells as it accumulates during the late stage of infection and promotes their lysis.³³⁷ While it is expressed at very low levels from rare mRNAs transcribed from the E3 promoter during the early phase of infection, it is expressed at very high levels from an mRNA with a tripartite leader transcribed from the MLP late in infection.³³⁸ This 101 amino acid protein is an integral membrane N-linked, O-linked palmitoylated glycoprotein that localizes to the nuclear membrane, endoplasmic reticulum (ER), and Golgi, where it interacts with the MAD2B protein.³⁹⁰ MAD2B is related to MAD2, which regulates the activity of the anaphase promoting complex ubiquitin ligase in response to the spindle assembly cell-cycle checkpoint during mitosis. But the function of MAD2B and how its interaction with the E3 protein leads to cell death are not known.

As discussed in the E1B section, the virus-induced ubiquitin ligase complex of E1B-55K-E4orf6-Elongins B/C-Cul5-RBX1 (Fig. 55.16) induces degradation of integrin $\alpha 3$, which appears to decrease attachment of infected cells to their

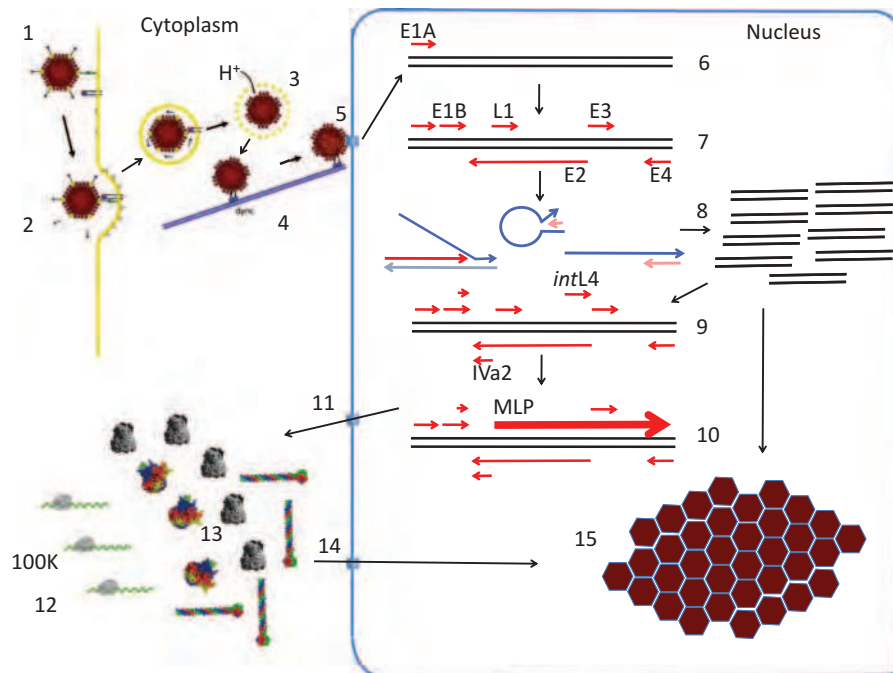

FIGURE 55.19. Summary of adenovirus infection cycle: (1) The globular fiber knob domains of human adenoviruses in species A, C, D, and E make high-affinity interactions with the extracellular domain of CAR (the coxsackie and adenovirus receptor). The fiber knob of HAdV-Bs interact with the extracellular domain of CD46. (2) Penton bases, now at high local concentration relative to the extracellular domains of α_v -integrins on the cell surface, make a lower affinity interaction that stimulates endocytosis of the particle via clathrin-coated pits as fibers dissociate from the pentons. (3) As the endosome matures and the interior becomes more acidic, conformational changes in virion proteins result in the release of pentons and peri-pentonial hexons. Multiple copies of protein VI pass through the open-particle vertices and lyse the endosomal membrane, releasing the partially uncoated virion into the cytosol. (4) The particle associates with dynein motor proteins that carry it along microtubules to the microtubule organizing center adjacent to the nucleus. (5) The partially uncoated particles associate with nuclear pore complexes (NPCs) and the viral DNA bound by protein VII is transported into the nucleus. (6) In a pre-early phase of infection, a transcriptional enhancer in the left 500 base pairs of the genome activates the transcription of early region 1A (E1A). E1A proteins are translated in the cytoplasm and transported back into the nucleus, where they stimulate the host cell to enter the S phase of the cell cycle and (7) activate transcription from E1B, L1, E2, E3, and E4 during the early phase. E1A, E1B, E3, and E4 proteins counter cellular antiviral defenses and stimulate cellular protein synthesis. (8) E2-encoded proteins replicate the viral DNA by the strand displacement mechanism. (9) DNA replication promotes an intermediate phase, during which additional regions—including IVa2 and intermediate L4—are transcribed. These encode viral transcription factors that bind to sites in the first intron of the transcript from the major late promoter, MLP, (10) greatly stimulating MLP transcription. L4-33K regulates RNA splicing. Multiple mRNAs are processed from the MLP transcript—encoding virion structural proteins and the 100K protein. (11) These late mRNAs are preferentially transported through NPCs to the cytoplasm. (12) 100K causes hypophosphorylation of the cap-binding translation initiation factor eIF4E, resulting in inhibition of host mRNA translation. However, the 201 base tripartite leader on all transcripts from the MLP permit initiation by hypophosphorylated eIF4E, resulting in exclusive translation of viral mRNAs into prodigious amounts of the virion structural proteins (13). These are transported into the nucleus through NPCs, where they assemble with replicated viral DNA into progeny virions. After assembly of ~100,000 progeny virions, the cell lyses, releasing them to carry out another cycle of infection.

substratum. This likely increases virus spread in the respiratory tract. As discussed previously, the interaction of E4orf1 protein with PDZ-domain-containing members of the membrane-associated guanylate kinase protein family disrupts tight junctions between epithelial cells and, consequently, probably aids in progeny virus dissemination.^{151,176} Finally, as discussed in the section Adsorption and Entry, tight junctions are also disrupted by free fiber trimers released from infected cells that interfere with CAR oligomerization.³⁵⁹ This also probably promotes the release of progeny virions to the airway lumen in the respiratory tract. Figure 55.19 presents an overview of the adenovirus infection cycle discussed previously.

PERSPECTIVES

As fundamental research on all aspects of adenovirus biology continues, the virus maintains its status as fertile ground for uncovering new knowledge, understanding, and insight regarding multiple aspects of animal cell biology and human antiviral defenses. Successively deeper understanding of the structure and assembly of the virion provides exquisite examples of macromolecular interactions and assembly. It also allows the design of adenovirus-based gene transduction vectors with engineered receptor-binding domains that promote infection of specific cell types. Replication over literally an astronomical number of

generations has led to the evolution of multiple viral proteins that interact with several cellular proteins, every one of which has profound functions in the biology of the cell. Through these interactions, the adenoviruses literally point a finger at cellular proteins and protein complexes that are nodes in the regulation of cellular processes. The viral proteins provide us with subtly engineered molecular tools for exploring these cellular processes. The large number of new references to fundamental advances in all aspects of adenovirus biology demonstrates that adenovirus research continues to be a productive and rewarding area of discovery. Adenovirus continues to have much to teach us.

HISTORY

During attempts to establish tissue culture lines from tonsils and adenoidal tissue surgically removed from children, Rowe and colleagues⁶¹³ recognized that a transmissible agent was causing degeneration of the epithelial-like cells. Thus, adeno-

viruses (Ads) were first cultured and reported as distinct viral agents in 1953.⁷⁸⁷

A nomenclature for Ads was adopted in 1956, and then Ads were reclassified in 1999.⁷⁴³ The family name is *Adenoviridae*, and there are four accepted genera: *Mastadenovirus*, from mammals; *Aviadenovirus*, from birds; and *Atadenovirus* and *Sia-**adenovirus*, from a broad range of hosts.^{50,141,743} A fish adenovirus falls into a fifth clade.¹⁴¹ Human Ads are divided into seven species, A, B, C, D, E, F, and G, based on serum neutralizing and hemagglutination epitopes, genome sequence and function, oncogenic properties in newborn hamsters, and pathology in humans. These species were previously referred to as groups or subgroups.

Historically, the human Ad isolates were designated as serotypes, based on neutralization of productive infection by homologous sera.⁵⁰ Recently, with the advent of high-throughput Ad genome sequencing and bioinformatics analysis, new insights have been obtained into Ad genome structure and taxonomy.^{141,262} Evolution of Ads seems to have been driven by not only sequence divergence but also frequent recombination between different serotypes.^{444,450,593,594,643,644,756,764,763} Researchers have taken the view that Ad isolates should be designated as *types* rather than *serotypes*, per definitions of the International Committee on Taxonomy of Viruses. Two similar but not exact proposals have been advanced to characterize Ads.^{17,642} With one proposal, for example, human Ad serotype 1 will be designated *type HuAdV-1*, with the “1” referring to hexon (the major capsid protein) identity. The rationale is that hexon should remain the major identifier “because it contains the major neutralizing epitope, which is targeted in molecular diagnosis”.¹⁷ With the other proposal, human Ad serotype 1 will become *type HAdV-C1*, with the “C” referring to species C.⁶⁴² In the current article we will use *serotype* to indicate *type* because serotype has been used in nearly all the literature. According to current standard nomenclature, “H” should precede the serotype number, for example, HAdV-5 for human serotype 5. For brevity, we will use “Ad5.”

There are 57 serotypes in the seven species of human Ads: species A (Ad12, 18, 31), species B (Ad3, 7, 11, 14, 16, 34, 35, 50, 55), species C (Ad1, 2, 5, 6), species D (Ad8 to 10, 13, 15, 17, 19, 20, 22 to 30, 32, 33, 36 to 39, 42 to 49, 51, 53, 54, 56), species E (Ad4), species F (Ad40 and 41), and species G (Ad52) (Table 56.1). Species B can be further divided into species B1 (Ad3, 7, 11, 16, 21, 50) and B2 (Ad11, 14, 34, 35). Ad52 to 57 are recent isolates. Ad52 (species G) was isolated from a patient with gastroenteritis.³⁴³ Ad53^{357,763} and Ad54³²⁶ are in species D and associated with epidemic keratoconjunctivitis (EKC). Ad56, species D, which caused a rare neonatal fatality and keratoconjunctivitis, seems to be a complex recombinant

TABLE 56.1 Infections Associated with Adenovirus Subgroup and Serotype

Subgroup	Serotype	Major site of infection
A	12, 18, 31	Respiratory, urinary, GI

GI, gastrointestinal.

of Ad9, 15, 26, and 29.⁵⁹⁴ Ad55, species B, isolated from a respiratory outbreak in China, is a recombinant between Ad14 (97% of genome) and Ad11.⁷⁶⁶ An isolate from the feces of a 4-year-old patient⁴⁴⁴ was recently proposed, based on computational analysis, to be Ad57 in species C: it has a fiber similar to Ad6 but a unique hexon.⁷⁶⁵ The genome of many human Ad serotypes has been sequenced.^{450,643,765,766,776} Also, the genome sequence of the Ad5 reference material (ARM) was published as a reference strain for Ad5-based vectors.⁶⁹¹ The genomes of serotypes within a species are highly related and are modestly diverged from species to species. This chapter will tend to concentrate on the relatively recent literature on Ad pathogenesis in humans. Some of the earlier literature can be found in the fourth and fifth Editions of *Fields Virology*.^{308,787}

INFECTIOUS AGENT

Propagation and Assay in Cell Culture

Primary human embryonic kidney (HEK) cells are probably the best host for the entire range of human Ads, but such cells are expensive and may be contaminated with adeno-associated virus. Continuous epithelial lines, such as HEp-2, HeLa, KB, HEK 293, and A549, are also highly sensitive. Ads in monolayer cell culture have a characteristic cytopathic effect (CPE). The cells round up, swell, and detach from the culture surface into grape-like clusters, and the nuclei become enlarged³⁶³ (Fig. 56.1). Eventually the cells lyse, leaving cell debris. This CPE is the result of the infection passing into the “late” stage of infection, when Ad DNA, messenger RNA (mRNA), and proteins are being made in large quantities and virions are assembling in the cell nucleus.

Biological Characteristics

Ads have a double-stranded DNA genome of ~36,000 base pairs (bp) enclosed by a protein capsid and with no membrane (see Chapter 55). The virion binds to specific receptors on the cell surface and enters the cell by endocytosis, and the genome is transported to the cell nucleus. “Early” genes are expressed, viral DNA replicates, “late” genes are expressed, virions assemble in the cell nucleus, and the cells lyse to release progeny

FIGURE 56.1. Cytopathic effect induced by adenovirus type 5 (Ad5) in human A549 lung adenocarcinoma cells. **A:** Mock-infected cells. **B:** Ad5-infected culture showing rounding, ballooning, and clustering of cells.

virus (see Chapter 55 and the legend to Fig. 56.10). There are about 20 early genes and 15 late genes. Ads increase glycolysis in continuous cell lines and thereby induce the cells to produce large quantities of acid. Rapid cytopathology can be induced within several hours of inoculating concentrated crude virus preparations and is not related to viral replication; rather, it is caused by the penton base component of the free viral penton capsomere.

Nuclear morphologic changes in infected tissue cells can be used for diagnostic purposes. The nuclear changes include overall enlargement and intranuclear inclusions that initially are Feulgen negative and eosinophilic but become Feulgen positive and basophilic as the infection progresses.⁷⁰ The Feulgen-positive inclusions contain Ads by electron microscopy (EM) (see Fig. 56.2), and it is the DNA within the viruses that

FIGURE 56.2. Electron microscopy (EM) of a nuclear inclusion body in a lung tissue cell from a fatal case of adenovirus pneumonia. The inclusion is full of virions, of which there may be as many as 10,000 particles per cell (EM, $\times 237,200$). (From Myerowitz RL, Stalder H, Oxman MN, et al. Fatal disseminated adenovirus infection in a renal transplant recipient. *Am J Med* 1975;59:591–598. Copyright 1975, with permission from Elsevier.)

contributes to the Feulgen stain. In addition, there are paracrystalline aggregates that contain viral protein without nucleic acid.⁴⁸⁴

Description of Key Antigens

The clinically predominant Ad antigens are the three capsid proteins: hexon, penton base, and fiber. Most early studies indicated that the hexon and to a lesser extent the fiber proteins contain most of the epitopes recognized by neutralizing antibodies, but there are neutralizing epitopes on penton base as well (reviewed in^{109,218,302,448,569,591,693,786}). The neutralization properties of polyclonal antibodies are often concordant with the inhibition of Ad-induced hemagglutination (HA) of selected red blood cells. However, the HA functions are the property of fiber (reviewed in⁵²¹), which usually must be linked to the penton base for complete HA to occur. Because of recombination within species in clinical isolates, it is not uncommon to isolate a virus that demonstrates discordant reactions in the neutralization and HA inhibition reactions.

One recent study of naturally infected humans found that the majority of neutralizing antibodies were against the hypervariable regions of hexon, but some were also against fiber and possibly penton base.^{591,693} In contrast, another recent study concluded that Ad5 neutralizing antibodies to fiber are more common than to hexon in the naturally infected population, but that immunization with a replication-defective Ad5-based vector raised more neutralizing antibodies to capsid proteins other than fiber.¹⁰⁹ Most studies in animal models infected with Ad5-based vectors have found that the predominant neutralizing antibodies are directed at hypervariable regions in hexon.^{404,591,810} Mechanisms by which neutralizing antibodies function include virus aggregation, virus destabilization, and blocking virus receptor interactions and integrin-mediated internalization (reviewed in⁶⁷⁰). One study with the Ad5 neutralizing hexon monoclonal antibody 9C12 reported that following infection and endosome penetration of the virus–9C12 complex, microtubule-dependent translocation to the microtubule-organizing center was inhibited.⁶⁷⁰ Another study with the same monoclonal antibody as well as polyclonal Ad5 neutralizing antibodies concluded that the cellular cytosolic protein TRIM21 binds to the antibody in the internalized antibody–virus complex and targets the virus to the proteasome for degradation.⁴⁵⁴

There are group- and type-specific epitopes on both hexon and fiber. Type-specific domains have been mapped to unique sequences in loop 1 (amino acids 281 to 292) and loop 2 (amino acids 441 to 455) of hexon by generating neutralizing antibodies to peptides from each of these regions. This epitope is referred to as the E determinant.⁴⁴⁸ Loops 1 and 2 had previously been shown to be on the surface of the virion by crystallography. Differences in the HA properties of rhesus and vervet erythrocytes for two important subtypes of Ad11 (Ad11p and Ad11a) have been related to nucleotide sequence differences in the shaft and knob region of fiber. The knob region of fiber, which has HA properties that are used for HI (hemagglutination inhibition) tests, includes the γ determinant.⁴⁴⁸ Ad11p and Ad11a have some differences in tissue tropism in that Ad11p can be persistent in the urinary tract and Ad11a causes acute respiratory tract infections. These properties of the whole virus may be related to the changes in fiber polypeptides that are otherwise identical for 92.3% of their amino acids.⁴⁶⁸

There are group-reactive antibodies that react with conserved domains of hexon from all human serotypes.⁵²⁹ These interactions were classically measured by the complement fixation (CF) test and were useful in identifying an agent as an Ad. Subsequent serologic techniques, such as immunofluorescent (IF) antibody and enzyme-linked immunosorbent assay (ELISA) determinations, were also capable of detecting group reactivity shared by most of the human Ads.

Ad-specific CD4+ T lymphocytes have been detected in peripheral blood monocytes (PBMCs) in nearly all naturally infected humans of all ages (reviewed by⁴⁰⁹).^{84,102,278,321,414,536,541,542,750} When PBMCs were stimulated in bulk culture (e.g., by incubation with intact Ad particles, Ad-infected cell extracts, or purified Ad proteins or with pools of peptides that span various Ad proteins), CD4+ T lymphocytes specific to hexon were identified from healthy donors.^{199,540,542,636,750,814} Other studies using peptides corresponding to parts of several Ad proteins identified a number of CD4+ T-cell epitopes, including the dominant human leukocyte antigen (HLA) DP4-restricted H910-924 epitope, located in the base of the hexon protein, conserved among Ad serotypes, and detectable in PBMCs from 78% of healthy adults analyzed.^{540,700} Many other CD4+ T-cell epitopes located in the conserved regions of Ad5 hexon and that are conserved across Ad serotypes have been identified that are recognized by PBMCs.^{410,411,636,750,813} In one study in which PBMCs from 44 healthy donors were analyzed, 10 CD4+ T-cell immunodominant hexon epitopes were detected in more than 50% of subjects examined.⁶³⁶ The HLA restriction element for some of these peptides is known.^{636,813} Although not as frequently found as are Ad- and hexon-specific CD4+ T cells, hexon-specific CD8+ T cells have also been detected in PBMCs from healthy donors; the cells are cross-reactive against various Ad serotypes, they secrete interferon- γ , and they have cytolytic activity in culture.^{199,320,321,345,410,414,669,700,813} CD4+ and CD8+ T cells specific to Ad proteins other than hexon, including penton base⁴¹¹ and the DNA polymerase,^{344,345} have also been identified.¹⁹⁹ There is increasing evidence that cytotoxic T lymphocytes (CTLs) specific to hexon are protective in humans.⁴¹⁰ Indeed, T-cell “lines” (mixture of CD4+ and CD8+ cells) specific to hexon (and other Ad proteins) have been shown to be effective by adoptive cell transfer in treating infection by various Ad serotypes in allogeneic hematopoietic stem cell transplant patients.^{198,411,413,813} The therapeutic effect is believed to be through the coordinated action of the adoptively transferred CD4+ and CD8+ T cells.⁸¹³

Infection of Experimental Animals

Human Ads are mostly species specific in their replication cycle, as are most Ads of other mammals or avian species. Even nonhuman primates are poor hosts for human Ads. Human species C Ads can replicate in the lung of cotton rats,²²⁷ and the pathogenesis of Ad pneumonia has been studied in these animals.^{54,227,574} An ocular model of infection with either Ad5 or Ad8 has been described in cotton rats, and the clinical manifestations, including subepithelial corneal opacities, were similar to epidemic EKC.^{359,730} The animals shed virus, developed specific antibodies to the infecting virus, and were able to spread the infection to control cotton rats. A similar ocular model was reported in New Zealand White rabbits after topical or intrastromal inoculations of Ad5.^{602,729} The virus appeared to replicate, and most of the animals developed a humoral immune

response. There were findings of blepharitis, conjunctivitis, iritis, corneal edema, and subepithelial corneal infiltrates that were consistent with immune-mediated clinical disease. The Ad5 New Zealand White rabbit model has been used to evaluate the anti-Ad activity of several compounds⁶⁰¹ including cidofovir and 2'-3' dideoxycytidine,⁶⁰³ *N*-chlorotaurine,⁶⁰⁴ and dexamethasone povidone-iodine.¹²³ Ad5 can also replicate in porcine tissues.⁷²³

A number of groups have explored the mouse as a model for pathogenesis of human Ads or as a model to evaluate oncolytic (replication-competent) Ad vectors for cancer gene therapy. The results from these studies have been mixed. Human Ads can infect cells of virtually all mammalian species including the mouse, especially if high multiplicities of infection are used (~100 plaque forming units [pfu] per cell). The early proteins (synthesized prior to Ad DNA replication) are expressed at good levels, but most workers have found that Ad DNA does not replicate (or barely replicates), and therefore that late genes are not expressed (or are expressed at very low levels). Nevertheless, there are reports that Ad5 or Ad2 can replicate to low levels in several mouse carcinoma cell lines^{221,258,503,772}; however, this is not a universal finding (e.g.,³⁴¹). When high doses of Ad5 were inoculated intravenously into CBA mice, there appeared to be several orders of magnitude of replication in the liver.¹⁶⁹ On the other hand, no replication was seen in the lungs of C57BL/6 mice following intranasal administration of Ad5.²²⁸ Also, little or no replication was observed in any organs following intravenous administration of an Ad5-based oncolytic vector in C57BL/6 mice⁸⁰¹ (this vector retains all Ad genes except some in the E3 region).

Ad5 replicates modestly in cotton rat cells,^{726,682} canine cells,⁷⁰³ porcine cells,³⁴¹ and Syrian hamster cells.⁷⁰⁵ In three Syrian hamster cancer cell lines, the burst size (virus yield per cell) was about 1,000, only 10-fold less than in A549 cells.⁷⁰⁵ In Syrian hamsters, about four orders of magnitude of Ad5 replication were seen in the lung following intranasal or intratracheal administration.^{292,487,705} Ad5 also replicates in the liver of Syrian hamsters following intravenous administration.⁸⁰¹

Because Syrian hamster tissues are quite permissive for Ad5 and there are numerous Syrian hamster cancer cell lines, Syrian hamsters have been used as a model to investigate the toxicology and antitumor efficacy of oncolytic Ad5-based vectors.^{157,369,705,707} Immunocompetent and immunosuppressed (by treatment with cyclophosphamide) hamsters bearing subcutaneous tumors formed by injection with various Syrian hamster cancer cell lines were treated by intratumoral injection with a variety of oncolytic Ad vectors.^{63,64,66,94,95,155,156,361,384,648,677,705,706}

In general, these studies show that oncolytic Ad5-based vectors suppress the growth of tumors, and that there is a rapid adaptive immune response to the vector that appears to eliminate the vector from the tumor. Syrian hamsters have also been used to study the biodistribution and toxicity of oncolytic Ad5-based vectors in advance of clinical trials.^{374,429,460,675,801}

Immunocompetent,^{159,727} newborn,⁸¹⁵ and immunosuppressed⁷²⁷ Syrian hamsters have been used to evaluate compounds to inhibit Ad5 replication. A mouse model was used similarly to test cidofovir against disseminated mouse Ad type 1 infection.⁴¹⁷

Human Ads inoculated into a variety of rodent species cause tumors. Ad12, 18, and 31 are highly oncogenic in newborn Syrian hamsters, and much has been learned about the

mechanism of action of the genes in the E1A and E1B regions from these viral models (see Chapter 55). The integrated Ad12 sequences in these hamster tumors are a model to understand epigenetic consequences of foreign DNA integrations.¹⁶⁰ Ad9 causes fibroadenomas and mammary sarcomas in rats, and an early region 4 gene seems to be important in this model.⁴⁰⁵

Functions of Adenovirus E3 Proteins

The proteins coded by the Ad E3 transcription unit are believed to provide protection of infected cells from the host antiviral response (Fig. 56.3) (reviewed in^{57,196,259,309,430,445,465,646,785}). The Ad2 or Ad5 E3-gp19K protein is a type I glycoprotein localized in the endoplasmic reticulum (ER) (reviewed in²⁵⁹). E3-gp19K binds to major histocompatibility complex class I (MHC-I) heavy chain in the ER, prevents transport of MHC-I to the cell surface by virtue of an ER retrieval signal on E3-gp19K, and prevents killing of Ad-infected cells by CTLs.^{14,82,131,582} E3-gp19K and its function are conserved among serotypes in all human Ad species²¹² except species A in which the E1A proteins cause down-regulation of MHC-I.³⁴⁰ E3-gp19K binds with higher affinity to HLA-A than to HLA-B, and it binds poorly if at all to HLA-C.^{212,259} E3-gp19K binds via a conserved domain (among Ad serotypes)^{213,641} to the outer surface of the peptide-binding groove on MHC-I molecules.^{259,437} E3-gp19K also binds to *transporter associated with processing* (TAP), prevents formation of the TAP–tapasin complex, and limits the inclusion of TAP into the peptide-loading complex of antigenic peptide, MHC-I, and chaperones.⁵² This property of E3-gp19K could possibly retard cell surface expression of MHC-I in individuals with HLA-B and HLA-C MHC-I molecules.²⁵⁹

Reduced expression of MHC-I could render Ad-infected cells susceptible to killing by natural killer (NK) cells. To potentially enhance this possibility, the Ad E1A proteins up-regulate ligands recognized by the NKG2D receptor on NK cells and sensitize the E1A-expressing cells to NK cell–mediated cell lysis.^{467,611} Multiple ligands for NKG2D are known, including the MHC-I chain-related A (MICA) and B (MICB) proteins. As is the case with MHC-I, E3-gp19K causes retention of MICA and MICB in the ER, prevents their transport to the cell surface, and reduces killing of E3-gp19K–expressing cells by NK cells.^{467,641}

The Ad E3-14.7K protein inhibits tumor necrosis factor (TNF)-induced cytotoxicity of Ad-infected cultured cells.^{232,232,234,305,306,579} E3-14.7K binds to cellular IKK γ /NEMO^{373,426} and is reported to modulate NF- κ B activity and inhibit TNF-induced apoptosis.⁴²⁶ E3-14.7K also is reported to bind to caspase 8.^{107,373} In addition, E3-14.7K inhibits internalization of TNF receptor 1 as well as formation of the death-signaling complex (DISC) that is required for TNF-induced apoptosis.⁶²⁵ Two studies report that E3-14.7K inhibits TNF-induced signaling through NF- κ B,^{90,426} whereas another study did not observe such activity for E3-14.7K.⁶²⁵ In a recent report, E3-14.7K stably expressed in mouse cells inhibited induction by TNF of the chemokine CCL2 (monocyte chemoattractant protein-1 [MCP-1]) by preventing phosphorylation of glycogen synthase kinase-3 β and recruitment of NF- κ B to the CCL2 promoter.⁶⁷⁸ Some researchers^{107,794} but not others⁷¹⁴ report that E3-14.7K inhibits apoptosis by Fas ligand. E3-14.7K also inhibits TNF-induced release of arachidonic acid,^{390,709,822} a property that might be important in reducing inflammation.

FIGURE 56.3. Schematic illustrating the E3 proteins and their functions. Each bar represents a protein, with the name of the protein above the bar. Colored bars without hatches are integral membrane proteins. The adenovirus death protein (ADP) was originally named the 11.6K protein.^{717,718} The receptor internalization and degradation (RID) protein was originally named E3-10.4K/14.5K, and RIDα and RIDβ were named E3-10.4K and E3-14.5K, respectively.⁷¹⁴

Two other E3 proteins, of 10,400 daltons (10.4K) and 14,500 daltons (14.5K), which were originally named E3-10.4K⁷¹⁶ and E3-14.5K,⁷¹⁵ respectively, form a molecular complex originally named E3-10.4/14.5K.⁷¹⁹ The E3-10.4K protein⁸⁸ and then later the E3-10.4K/14.5K complex⁷¹⁹ were reported to be required to clear the epidermal growth factor receptor (EGFR) from the cell surface (Fig. 56.4). The E3-10.4K and E3-14.5K proteins were later renamed *receptor internalization and degradation* (RID)α and RIDβ, respectively, when it was shown that these proteins also are able to cause the internalization and lysosomal degradation of not only EGFR but also cell surface Fas,^{180,464,662,714} TRAIL receptor 1,^{49,720} and TNF

receptor 1.^{110,111} RID inhibits cytolysis induced by Fas ligand (i.e., by an agonist antibody)^{428,662,714} and TNF.^{233,390,812} RID, functioning in concert with the E3-6.7K (6,700 daltons) protein, also down-regulates TRAIL receptor 2 from the cell surface.^{49,427} One laboratory⁴⁹ but not another⁴²⁷ reported that E3-6.7K is required together with RID to down-regulate TRAIL receptor 1. A cytosolic tyrosine sorting motif (YXXΦ) in RIDβ^{110,428} and a cytosolic dileucine motif²⁸⁶ and tyrosine-containing motifs¹¹⁸ in RIDα are required for these proteins to function.

RID also has been shown to inhibit TNF-induced translocation of cytosolic phospholipase A₂ to membranes (from where arachidonic acid is generated)³⁹⁰ and to inhibit

A

B

FIGURE 56.4. Clearance of the epidermal growth factor receptor from the surface of human A549 cells by Ad5. In mock-infected cells (A), the receptor is abundant on the cell surface, whereas in Ad5-infected cells (B), the receptor has been internalized into endosomes. The internalization of the receptor is mediated by the E3 receptor internalization and degradation (RID) complex of proteins.

lipopolysaccharide- and interleukin-1 β -mediated signaling responses.¹⁵⁰ Thus, both RID and E3-14.7K might function *in vivo* to inhibit inflammatory responses associated with infection.

In contrast to most laboratories who have studied RID, one laboratory has reported that RID α can function in the absence of RID β to down-regulate EGFR.^{118,293,645} This laboratory also reported that RID α alone is able to regulate endosome maturation by mimicking guanosine triphosphate (GTP)-Rab7⁶⁴⁵ and to activate an autonomous cholesterol regulatory mechanism.¹¹⁷ Possible explanations for how RID α , RID β , and the RID α /RID β complex (i.e., RID) could function independently have been discussed.⁶⁴⁵

As mentioned, the E3-6.7K protein is required together with RID to down-regulate TRAIL receptor 2 from the cell surface in Ad-infected cultured cells.^{49,427} In transiently or stably transfected Jurkat cells, E3-6.7K alone inhibited apoptosis induced through Fas, TNF receptor, and TRAIL receptors and prevented TNF-induced release of arachidonic acid.⁴⁸⁰ Further, E3-6.7K was shown to interact with calcium modulator and cyclophilin ligand (CAML), a calcium-modulating protein,²⁴¹ to prevent calcium efflux from the ER, maintain calcium homeostasis, and inhibit apoptosis induced by thapsigargin (which inhibits calcium uptake by the ER).^{241,480}

The functions for the E3 proteins as described previously have been determined by studies in cell culture, and the question arises as to whether the E3 proteins have these same functions or other unknown functions *in vivo* (animal models and humans). Some and perhaps all of the E3 proteins are not essential for Ad5-based oncolytic vectors to replicate in Syrian hamsters⁷⁰⁵ or in cancer patients, but there is good evidence that E3 proteins have functions *in vivo*. In one study, expression of all the E3 proteins from a replication-defective Ad vector prolonged transplants of human cells in immunocompetent mice.⁷²⁴ In another study, the entire Ad2 E3 region stably expressed in an immortalized Gunn rat hepatocyte cell line protected against allograft rejection following transplantation into rats.⁴⁵⁸ This protection correlated with reduced Fas expression and inhibition of Fas-mediated apoptosis in the transplanted cells (which could be mediated by RID). Expression of E3-gp19K plus RID by lentivirus vectors in an insulin-producing β -cell line corrected diabetes in allogeneic mice, whereas the cell line without E3-gp19K plus RID did not protect.³⁸³ In transgenic mice, the entire Ad2 E3 region that was placed under the control of the rat insulin promoter (RIP) for targeted expression in murine pancreatic islet cells prevented autoimmune diabetes in a virus-induced (lymphocytic choriomeningitis virus) murine model of type I diabetes or in non-obese diabetic (NOD) mice.^{179,755} In further studies in which all E3 genes except E3-gp19K or except the E3B region genes (E3-RID plus E3-14.7K) were expressed from the RIP in transgenic mice, one study found that E3-gp19K but not the E3B region genes prevented autoimmune diabetes,³¹⁰ but another study obtained the opposite result.⁵⁶⁶ In studies addressing E3-14.7K, the gene for E3-14.7K, which was cloned into vaccinia virus together with the *tnf* gene, increased the virulence of the vaccinia virus carrying the *tnf* gene alone by reversing the antiviral effects of TNF.⁷³¹ In other studies, a transgenic mouse was constructed in which E3-14.7K is expressed selectively in the distal respiratory epithelium (alveolar and bronchial) from the surfactant protein B promoter.²⁶⁴ E3-14.7K protein suppressed pulmonary epithelial cytotoxicity and lung

inflammation in response to respiratory infection with a replication-defective Ad vector or to intratracheal administration of lipopolysaccharide.²⁶⁴ In an influenza virus study, E3-14.7K reduced expression in the lung of CCL2, a chemokine that functions in recruitment of inflammatory monocytes and lymphocytes.⁶⁷⁸ E3 genes were required to reduce inflammation in an Ad5 pneumonia model in cotton rats²²⁷ and mice.⁶⁷⁶ The E3-6.7K plus E3-gp19K proteins were required to prolong persistence of an oncolytic Ad in Syrian hamsters.⁶⁵ These various studies suggest that E3 proteins function *in vivo* in a manner consistent with their functions seen *in vitro*.

PATHOGENESIS AND PATHOLOGY

Ad infection causes inhibition of cellular DNA, mRNA, and protein synthesis. The infected cell degenerates in specific ways that help the pathologist diagnose Ad infection on biopsy or autopsy tissue.⁵⁰⁰ The respiratory epithelial cells that are affected during Ad pneumonitis have enlarged nuclei containing amphophilic or basophilic inclusion bodies surrounded by thin rims of cytoplasm. Some of these cells are referred to as *smudge cells* and contrast with those infected cells with nuclear inclusions but intact nuclear membranes. As in tissue culture, the epithelial cells are the primary target for Ad cytopathology *in vivo*.⁷⁰

One of the Ad structural proteins, the penton base, made in much larger excess than needed for the assembly of Ad, binds to the $\alpha_v\beta_3$ and $\alpha_v\beta_5$ integrins via an arginine-glycine-aspartate (RGD) motif in penton base²⁸ and causes cells to detach rapidly from monolayer cell culture dishes.⁷⁸⁰ This effect can be demonstrated even in cells that are not directly infected with Ads; it has been postulated that this protein might be involved in pathogenesis. It had been thought that the penton cell-rounding effect led to cell death, but it now appears that the cells are viable upon removal of the viral protein.⁵⁰⁸ Although the importance of penton in human disease has not been determined, it has been found in the blood of several fatal cases of Ad pneumonia.⁴⁰⁰

Ad-induced changes at the level of single cells result in considerable organ toxicity during serious tissue invasion by Ads. Necrotizing bronchitis, bronchiolitis, and interstitial pneumonia, as well as fibrin and hyaline membranes within the alveoli, characterize Ad pulmonary syndromes.¹⁶⁸ Comparable lesions occur within the conjunctiva, in which exudative and mononuclear infiltrates are found. However, the lesions occur beneath the epithelium, so that ulceration or neovascularization of the cornea usually does not occur.^{335,478}

Proliferative responses similar to transformation have not been recognized in acute Ad infections in humans. However, lymphatic tissue is often hypertrophied, and active germinal centers are found. For example, the appendices of children undergoing surgery to correct bowel obstruction found in intussusception may be associated with enlarged mesenteric lymph nodes and Ad isolation from stool specimens.⁸⁰⁷ These lymphocyte changes are often in close proximity to areas of desquamated epithelial cells in which typical viral inclusions may be found. The inclusions contain viral particles in crystalline arrays that are visualized by electron microscopy (EM). Some of the lymphocytes are probably CD8+ CTLs that recognize proteolytic peptide products of viral proteins.

FIGURE 56.5. Some of the receptors used by human adenoviruses (Ads). CAR, sialic acid, CD86/CD80, CD46, and MHC-1 are membrane proteins. Other ligands are present in a soluble form, such as lactoferrin and coagulation factor X, which are used as a bridge between the virus and the cell to target the liver. The receptor used depends on the Ad type and the targeted tissue. CAR, coxsackievirus B and adenovirus receptor; HSPG, heparan sulfate proteoglycans. (From Enaff D, Salinas S, Kremer EJ. An adenovirus traffic update: from receptor engagement to the nuclear pore. *Future Microbiol* 2011;6:179–192, with permission.)

Entry into the Host

Ads enter susceptible hosts by the mouth, nasopharynx, or ocular conjunctiva. Recent experiments have defined the Ad receptors (Fig. 56.5) (reviewed in ^{406,469,521,770,817}). The cell protein named CAR (coxsackie-adenovirus receptor) is a receptor shared by these two groups of unrelated viruses and is the target of fiber in many if not all serotypes in species A, C, D, E, and F.^{55,55,597} CAR is present on tight junctions of polarized cells where it mediates cell–cell adhesion. Species B Ads can be differentiated based on their receptor usage.⁷³² Species B, group 1 (Ad16, 21, 35, 50) viruses nearly exclusively utilize CD46 as a receptor.^{253,457} Initially, Ad37, a species D Ad, was also thought to use CD46,⁷⁹¹ but recent data suggest that GD1a glycan is the more likely major receptor for this virus.⁵²⁵ CD46 (also known as membrane co-factor protein) is expressed in virtually all cells where it acts as a co-factor for inactivation of the complement components C3b and C46. Species B, group 2 (Ad3, Ad7, 14) viruses share desmoglein 2 as the high-affinity receptor.^{769,770,771} Desmoglein 2 is a calcium-binding transmembrane glycoprotein belonging to the cadherin protein family. When the Ad fiber binds to desmoglein 2, there is opening of intercellular junctions that results in increased access to receptors trapped deep within the junction (i.e., CD46 and Her2/*neu*).⁷⁷⁰ Further, such dissociation of the intercellular junctions may facilitate the lateral viral spread in epithelial cells and, potentially, the penetration of Ad into subepithelial cell layers and the bloodstream. Lastly, species B, group 3 (Ad11) viruses preferentially interact with CD46 but also utilize desmoglein 2 if CD46 is blocked.⁷⁷⁰

Heparan sulfate glycosaminoglycans, which are long heterogeneous, heavily sulfated carbohydrates that are abundant within the extracellular matrix, can mediate the CAR-independent binding of Ad2 and Ad5 to cells, but it is not known if these are *bona fide* receptors.⁸¹⁷ The class I MHC molecule has been proposed as a second receptor for Ad5³⁰⁴ but has not been confirmed by other groups.^{142,463} Three species D Ads, Ad8, Ad19, and Ad37, all major causes of EKC, appear to bind to α 2,3-linked sialic acid present in the GD1a ganglioside on the corneal cell surface.⁵²⁵ Several integrins participate in Ad uptake into cells by interacting with the RGD motif on the Ad penton base protein.⁸¹⁷

Most of the studies described previously were conducted *in vitro*. Recent studies of systemic administration of Ad vectors in mice raise the possibility that infection of tissues *in vivo* may be different (see section on Adenoviruses as Vectors for Vaccination and Gene Therapy). These studies propose a CAR-independent model in which Ad infection of murine hepatic cells occurs through binding of Ad to blood factors, especially factor X, directing the complexes to hepatocellular receptors including heparan sulfate proteoglycans (Fig. 56.5). Whether this pathway operates in humans is a key²⁸¹ question. Recent studies clearly demonstrate that all of the tested species of Ads, except for the species D viruses, efficiently bind human factor X.⁷⁵⁷ The high-affinity interaction of Ads with factor X may facilitate “bridging” the hexon protein in the Ad capsid to heparan sulfate proteoglycans expressed on the surface of hepatocytes.^{352,757} The Ad–factor X complex binds to the cell surface through the serine protease domain of factor X and not through a direct interaction of the virus with the cell surface.⁷⁵⁷ Once bound to the cell surface, efficient and rapid intracellular transport of the Ad, though, remains dependent upon engagement of α_v integrins via the penton base protein.⁷¹

The lower serotypes, Ad1, 2, 5, and 6, are ubiquitous, particularly in young children, and may be shed for months, especially in the stool, which is probably responsible for the endemic spread of these agents by the fecal–oral route to new pools of susceptible infants and children.²⁰⁵ An epidemic form of Ad keratoconjunctivitis (EKC) has been spread in swimming pools²⁰⁷ from contaminated water and in medical settings³³⁶ from Ad-infected ophthalmologic instruments. A third pattern of spread was unique in the military setting, occurring during the early period after induction into service. Ad4 and Ad7 caused acute respiratory distress (ARD), including pneumonia, and were the result of air-borne inoculation of the respiratory tract¹⁶⁸ as well as acquisition after contact with contaminated surfaces in living quarters.⁶¹⁵

Site of Primary Replication

It is clear from the original findings of Ads in tonsils and adenoids that these tissues of the oropharynx are a major initial site of replication for the entering Ads. For serotypes causing

respiratory disease, the initial replication most likely occurs in the nonciliated respiratory epithelium, although some limited replication and persistence can also occur within lymphocytes (reviewed in⁴⁴⁵). These conclusions are based not on careful observations of cells *in situ* but on the cells in which Ad replicates in tissue culture. Ciliated respiratory epithelium of the lower airway is difficult to infect with Ads through the apical surfaces, which do not contain the CAR receptor; however, disruption of the integrity of cell–cell contact allows basolateral infection of such polarized epithelial cells using CAR.^{565,768}

Spread of Virus and Tissue Tropism in the Host

Most of the manifestations of Ad infection are locally in the eyes and pharynx, but contiguous extension into the lungs results in some cases. One possible molecular mechanism facilitating the spread of the virus over respiratory epithelia is that the fiber protein, which is synthesized in great excess in the infected cell and is released when the cell is lysed, binds CAR on the basolateral surface. This binding disrupts the CAR homodimers in tight junctions, thus increasing paracellular permeability. This in turn allows the virus to escape onto the apical surface of the respiratory epithelium, thereby making it possible for the virus to infect other areas of the respiratory tract.⁷⁶⁷ Likewise, for the species B viruses that bind to desmoglein 2, binding to desmoglein 2 resulting in dissociation of the intercellular junctions may facilitate spread of the virus locally and into deeper tissue layers, allowing access to the bloodstream.⁷⁷⁰ Even in the nonreplicating mouse model of human Ad infection, the virus can cause inflammation in the lungs, which is strong evidence for direct extension into these target organs.^{228,676} Ads have been cultured from the blood during fatal Ad respiratory disease, suggesting viremic spread in some situations (see the section later on immunocompromised patients). As CAR is present on endothelial cells, viremia might be promoted by the fiber protein through the mechanism described earlier. The successful use of oral, live, microencapsulated Ad vaccines by the military to prevent ARD suggests that if the respiratory tract can be physically bypassed by Ad4 and Ad7, intestinal replication of the virus causes an immunizing rather than a virulent infection.¹²⁹ Although most Ads replicate in the intestine without causing gastroenteritis, Ad40 and 41 are responsible for intestinal disease. Ad disease in the urinary bladder, primarily by species B Ads in immunocompetent hosts, suggests that the virus probably is viremic at some stage in order to reach this organ. There is no evidence for ascending infection for these species B serotypes, which are less commonly found in the intestine and are more common in young males than in females. The route of infection of the liver, especially in immunosuppressed liver transplant recipients, is unknown, but some patients might be infected by latent Ads that are present in cells such as lymphocytes in the transplant.

Immune Response

Various aspects of the immune response to Ads have been described in other sections, as have mechanisms that the virus uses to evade the immune response (see Fig. 56.3 and section on Functions of Adenovirus E3 Proteins). The innate response to Ad also has been reviewed^{439,504} (see section on Adenoviruses as Vectors for Vaccination and Gene Therapy). In the airways, the virus must penetrate the surface fluid, and sialic acid present in the mucus may bind and inhibit species D Ads that use sialic acid as a receptor.^{342,525} The virus must also survive chemical defenses of

the host. These include a large variety of antimicrobial peptides that are able to neutralize microbes directly. Among these peptides are the defensins, a family of small cationic amphipathic peptides divided into two classes, α -defensins and β -defensins (reviewed in²⁷³). The α -defensins HNP1 and HD5 were shown to neutralize Ad serotypes in species A, B1, B2, C, and E, but not in species D and F.^{270,671,672} The defensins bind Ad particles outside the cell, block uncoating of the virion, and restrict the release of virions from endocytic vesicles.⁶⁷¹ Thousands of molecules of α -defensins bind to a sensitive serotype; neutralization of the virus depends on binding to critical determinants in a region spanning the fiber and penton base proteins.⁶⁷² Binding to these determinants is proposed to prevent the release of fiber from the virion, the first step in the virion uncoating process within the endosome.⁶⁷² HNP1 is expressed primarily in neutrophils, monocytes, lymphocytes, and natural killer cells, while HD5 is expressed mainly by Paneth cells in the intestine.^{273,671} It is not known if these or other defensins play a role in Ad infections in humans.

With respect to cellular defenses, alveolar macrophages and Kupffer cells play an important role in elimination of Ad vectors from the lung and liver, respectively, in murine models^{439,504} (Fig. 56.6) (see section on Adenoviruses as Vectors for Vaccination and Gene Therapy). These cells take up the vectors rapidly and secrete inflammatory cytokines such as TNF, interleukin-6 (IL-6), and IL-8. A robust inflammatory response characterized by early cytokine (IL-1 β , IL-6, interferon- γ [IFN- γ], IL-12, and TNF) and chemokine release as well as neutrophilic and monocytic infiltration have been described in the murine pneumonia model after nonpermissive infections with species C Ads.^{228,349} Increased levels of IL-6, IL-8, and TNF have also been associated with Ad infection in children.⁴⁷⁶ A recent study suggested that there may be specific cytokine signatures in pediatric stem cell transplant recipients with localized and invasive Ad infection. Patients with invasive infections had increased levels of the pro-inflammatory cytokines IL-1 β , IL-6, IL-8, IL-12, IFN- γ , and TNF- α , as well as IL-17, macrophage inflammatory protein-1 α (MIP1 α), oncostatin M (OSM), and IFN- γ -inducible protein 10 (IP10).²⁷² Invasive Ad infection was also associated with the simultaneous release of the cytokines IL-1 β , IL-17, IL-18, OSM, MIP-1 α , and IP10.²⁷²
